ABSTRACT (246 words):

Objective: To assess the nine-month HIV-free survival of children with two strategies to
25 prevent HIV mother-to-child transmission.

Design: Non-randomized interventional cohort study.

Setting: Four public health centers in Rwanda.

Participants: Between May 2005 and January 2007, all consenting HIV-infected pregnant
women were included.

30 Intervention: Women could choose the mode of feeding for their infant: breastfeeding (BF)
with maternal highly active antiretroviral therapy (HAART) for six months or formula
feeding (FF). All received HAART from 28 weeks of gestation. Nine-month cumulative
probabilities of HIV transmission and HIV-free survival were determined using the Kaplan-
Meier method, and compared using the log-rank test. Determinants were analyzed using a
35 Cox model analysis.

Results: Of the 532 first-live born infants, 227 (43%) were BF and 305 (57%) were FF.
Overall, seven (1.3%) children were HIV-infected of whom six were infected *in utero*.
Only one child in the BF group became infected between month 3 and month 7,
corresponding to a 9-month cumulative risk of postnatal infection of 0.5% (95% CI 0.1-
40 3.4%; P=0.24) with BF. Nine-month cumulative mortality was 3.3% (95% CI 1.6-6.9%) in
the BF arm group and 5.7% (95% CI 3.6-9.2%) for the FF group (P=0.20). HIV-free
survival by nine months was 95% (95% CI 91-97%) in the BF group and 94% (95% CI 91-
96%) for the FF group (P=0.66), with no significant difference in the adjusted analysis
(adjusted hazard ratio for BF: 1.2 (95% CI 0.5-2.9%).

45 Conclusions: Maternal HAART while BF could be a promising alternative strategy in resource-limited countries.

Key words: Africa, PMTCT, HIV, antiretroviral, breastfeeding, formula feeding, postnatal transmission

INTRODUCTION

In developed countries, comprehensive prevention of mother-to-child transmission(PMTCT) programs that use antiretroviral treatment(ART) prophylaxis and alternatives to breastfeeding(BF),
55 have been shown to be very effective, resulting in overall HIV perinatal transmission rates of less than 2% [1]. Similarly, low rates of perinatal transmission have been demonstrated in PMTCT programs in low-income countries[2-4]. However, when BF is employed, especially for extended periods and mixed with formula feeding(FF), subsequent transmission through BF clearly reduces the long-term efficacy of these prophylactic regimens[5-8]. Exclusive breastfeeding(EBF) with
60 early cessation[9] and FF are two conceivable alternatives to prevent postnatal HIV transmission[4]. Several studies from low-income countries have reported postnatal transmission rates of less than 2% using alternatives to BF without a higher overall mortality rate[2, 10]. However, in operational settings, these alternatives have shown a worrying increase in overall mortality among FF children, probably due to the lack of access to clean water, incorrect dilution
65 of formula, and inadequate access to formula or postnatal follow-up[11-12]. As a result, current World Health Organization(WHO) guidelines recommended EBF with early weaning if replacement feeding is acceptable, feasible, affordable, sustainable and safe [13]. Unfortunately, there are still concerns: EBF cannot completely avoid HIV transmission, but early weaning may lead to an increased morbidity in children[12]. With the increased access to ARV in Africa, two
70 other approaches could be conceivable as well: giving prophylactic antiretroviral treatment to breastfed children born to HIV positive mothers[14-16] or to provide maternal highly active antiretroviral treatment(HAART) while BF[2, 17-18]. Although several studies provide indirect evidence for the efficacy of this latter intervention[19-21], well-designed studies evaluating the efficacy of this strategy in poor countries are virtually non-existent or on-going. No single study

75 has formally compared maternal BF with HAART to FF within the same cohort in resource-limited countries.

Therefore, we implemented an interventional cohort study to assess these two interventions to prevent postnatal MTCT of HIV-1 in Rwanda: BF combined with maternal HAART for a maximum duration of six months versus exclusive FF. The purpose of this paper is to report the efficacy of these interventions based on HIV-1 transmission, mortality and HIV-free survival until
80 nine months of age.

METHODS

Study Design and Setting:

This was a non-randomized, interventional cohort study, named “AMATA”, which means
85 “milk” in the local language (Kinyarwanda). It was conducted at four government-run health
facilities: one rural health centre (70 km from Kigali, the capital city), one semi-rural health centre
(15 km from Kigali) and two urban sites in Kigali. Each of these four sites had antenatal care
services with PMTCT programs in place, providing access to treatment for HIV infection. Routine
HIV testing and HAART are provided free of charge in Rwanda.

90 ***Study population:***

Between May 2005 and January 2007, all HIV-infected pregnant women entering the PMTCT
programs in these four centres were invited to participate in the study from 28 weeks of gestation.
The women were counselled about the risk of higher morbidity with FF and the risk of HIV
through BF during two information prenatal sessions; those consenting to participate were given
95 the choice of infant feeding mode at inclusion, prior to delivery.

Interventions

All enrolled women received HAART from 28 weeks of gestation irrespective of the study
group. In line with the Rwandan national protocol, pregnant women with CD4 cell count <350
cells/ μ L and/or WHO clinical stage 4 were considered eligible for lifelong HAART, consisting (in
100 2005) of combined therapy with stavudine(D4T), lamivudine(3TC) and nevirapine(NVP). For the
remainder (WHO clinical stage 1, 2, 3 and CD4 cell count >350/ μ L), a prophylactic HAART
regimen containing zidovudine(AZT), 3TC and efavirenz(EFV) was started. EFV was chosen to
avoid the hepatotoxicity due to NVP for women having high CD4 cell counts[22]. AZT was
preferred over D4T in prophylactic HAART given its well documented efficacy in PMTCT.

105 After inclusion, those choosing FF had specific education sessions with the counsellors on safe
preparation of formula, which was provided free of charge until six months of age. These women
were also informed that they would be given an injection of 5 mg oestradiol just after delivery, to
help suppressing the breast milk production. In the BF group, women were counselled to
exclusively breastfeed until six months and then to perform rapid weaning. A supplement of
110 “sosoma” (mixture of soya, sorghum and maize) was given during the weaning period for one
month and was also given to the FF group. All food supplementation was stopped at seven months
unless severe malnutrition (weight-for-age below the fifth percentile) was diagnosed, after
excluding underlying medical problems. We used the Centers for Disease Control and Prevention
curves[23], as the 2006 international WHO curves[24] were not available at the start of the study.
115 After birth, prophylactic HAART was stopped for the non lifelong eligible women that had opted
for FF unless they became eligible for HAART in between. For BF women, prophylactic HAART
was given until seven months of age (until one month after weaning) to protect infants against the
risk of postnatal transmission associated with mixed feeding if abrupt weaning was not done. In
each case, a backbone of AZT and 3TC was given for seven days after stopping NVP/EFV, to
120 reduce the risk of resistance[25].

Following WHO recommendations, all newborn infants exposed to HIV received NVP 2 mg/kg at
birth and AZT 4 mg/kg twice-daily for seven days. At six weeks of age, cotrimoxazole was given
to all infants until nine months of age and continued after for those infected[22].

125 ***Follow-up procedures:***

Follow-up of mother-infant pairs was done by the AMATA team, consisting of physicians, nurses
and counsellors. Mother-infant pairs were examined clinically at birth (within 48 hours) and

130 follow-up visits were scheduled at fifteen days, six weeks and three, six, seven and nine months
post-partum. At each visit, adherence to HAART (pill count and questionnaires) and the feeding
method were assessed by maternal interview and clinical examination and women were counselled
135 accordingly. Breast health and feeding techniques were evaluated at each visit. If a breast-fed
infant had received any liquids or solids even once (with the exception of drugs), they were then
considered to have received “mixed feeding”, using the WHO definitions[26]. In case of
problematic or insufficient BF, the need to add additional feeding was discussed and mixed
135 feeding was an acceptable option. All women were counselled about family planning; those on an
EFV-containing regimen were given three-monthly progesterone injections.

All care was provided for free, and transportation costs were reimbursed by the project.

CD4 cell count and HIV-RNA plasma viral load(VL) of all women were measured at inclusion, at
delivery (less than 48 hours after having given birth) and at six months postpartum.

140 CD4 cell count was done using a FACSCalibur instrument (BD Bioscience, Becton, Dickinson
and company, USA). VL tests were done with the Real-time polymerase chain reaction(PCR)
testing on COBAS TaqMan® 48 Analyzer (Roche, Switzerland).

The HIV status of the infant was established with a HIV-1 DNA PCR assay using the Amplicor
technique (version 1.5, Roche Molecular Systems, Pleasanton, CA).

145

Diagnosis of HIV infection in children:

HIV DNA PCR tests were performed in children at birth, at six weeks, three months, seven and
nine months of age. Infants were defined as having been infected *in utero* if the HIV-1 DNA PCR
was positive within 48 hours of life and confirmed to be positive in the next test. Transmission was
150 considered to have occurred peripartum if a negative result at birth was followed by a positive

result at six weeks of age. The blood test done at day 15 was stored and performed only in case of different results between birth and six weeks PCR tests. Children with a positive HIV DNA PCR after day 15 were considered infected through breast milk if blood samples from birth and day 15 were negative. Every positive HIV test for children was confirmed by a second positive test before
155 a final diagnosis of HIV infection was accepted.

Mortality and morbidity data were obtained through hospital inpatient and outpatient records or by interview of the family member at each scheduled visits.

Main Outcome Measures:

Three main outcomes were measured at nine months of age among the liveborn children:

- 160 - Cumulative incidence of mother-to-child HIV transmission (peri-natal and postnatal)
- Cumulative infant mortality.
- Cumulative incidence of HIV-free survival: HIV infection or death whichever came first.

Statistical Analysis:

Every first-born liveborn child was included in the analysis in an intent-to-feed analysis,
165 BF+HAART or FF. The allocation to a feeding group was based on the feeding option chosen before delivery. All newborns that died before 48 hours of life linked to anoxia and prematurity before any feeding were not included in the analysis, to exclude deaths unrelated to the feeding option. The Student t-test, Wilcoxon rank-sum test, χ^2 test and Fisher's exact test were used to determine differences in means, medians values and proportions between groups. Cumulative
170 probability of events in the first nine months of life was calculated using Kaplan-Meier estimates with 95% Confidence Intervals(CI). This was appropriate since intervals between tests were less than three months[27]. Comparisons were made using the log-rank test. Infants who were lost to follow-up(LTFU) before reaching study end points were recorded at the date of their last HIV test

available. LTFU was defined as having missed planned appointments after having been actively
175 sought at home. The timing of acquisition of infection was estimated to have occurred midway
between the dates of the last negative and the first positive test. Determinants for nine-month HIV-
free survival were explored using a Cox model adjusted on the following variables : infant feeding
modalities, and co-variants: maternal CD4 count at delivery, time on HAART prior to delivery,
access to clean water, level of the mother's education, mode of delivery and birth weight and sex
180 of the infant. VL at delivery was not included, since data were missing for 18% of women.
Data were entered and stored using Access TM software, data analysis was done with Epi Info
TM(version 3.3.2), SPSS TM(version 16) and Stata TM(Version 9).

Sample size

The main judgement criterion was HIV-free survival, expected to be 95% overall at nine-months
185 of age. To be able to detect a 7.5% difference in HIV-free survival (a constant HR of 0.38) with a
power of 80% [28], 205 patients needed to be included in each group. Allowing for 10% LTFU, we
decided to include at least 225 pregnant women in each group.

Ethics

The study was designed and conducted in collaboration with the Rwandan Ministry of Health.
190 The National Ethical Committee of Rwanda, having an international registration, approved the
study with annual evaluation of the study progress reports and re-evaluation of the protocol.
An informed consent has been obtained for all patients included in this cohort.

RESULTS

195 *Study population*

From May 2005 to January 2007, 562 HIV-positive pregnant women were included in the study, of whom 240(42.7%) preferred BF under HAART and 322(57.3%) women chose FF. Eleven(2.0%) women were LTFU prior to delivery, and 551 infants were born during the study, of whom 11 were twins (second born excluded) and 14(2.5%) were stillborns.

200 Overall, five(1.0%) newborns died within 48 h of life (four were premature, and one infant died on the second day of a neonatal infection that was clinically present at the time of birth; the mother had fever during expulsion). None of these five deaths were related to feeding exposure and were excluded from further analysis. Therefore 532 mothers-infant pairs were included in this analysis (Figure 1).

205 Delivery characteristics of these women and infants are summarized in Table 1. Women choosing BF were slightly younger, had higher CD4 cell count and were less likely to be eligible for lifelong HAART than women choosing FF. They had also less access to clean water. VL at delivery was similar in both groups but 95(17.8%) VL were missing at delivery due to laboratory technical problems. Women in the FF were also more likely to
210 have started life-long ART prior to inclusion in the study. Overall, 256(48.1%) women were on HAART for life after inclusion.

Tolerance of and adherence to the interventions

No mother interrupted her HAART treatment, although 11(2.1%) required drug substitution due to toxicity, one during pregnancy and ten after delivery. Of all these side
215 effects, seven were due to AZT-related anaemia, and two were due to D4T-related

lipodystrophy. In addition, one woman interrupted EFV treatment due to a severe depression and one case of rash due to NVP was observed. No HIV-related deaths were reported. Adherence to exclusive BF was very good (94.2%). None of the infants of the 13 women who practiced mixed feeding were infected.

220 **Outcomes**

Overall, seven children were infected with HIV-1 of which six *in utero* (three in each infant feeding group). Only one child in the BF group became infected between month 3 and month 7 and no child acquired HIV infection between birth and nine months in the FF group. In the BF group, the cumulative probability of HIV-1 transmission at six weeks and
 225 nine months was 1.3% (95% CI 0.4-4.1%) and 1.8% (95% CI 0.7-4.8%), respectively. In the FF group, these cumulative probabilities were similar at six weeks and nine months estimated to be 1% (95% CI: 0.3-3.0%). Over the first nine months, the probability of HIV-1 transmission was not statistically different between both groups (log-rank test, P=0.43). The one infant who acquired HIV infection in the BF group represented a cumulative risk
 230 of postnatal infection of 0.5% (95% CI 0.1-3.4%; P=0.24) at nine months of life. Although the infecting BF mother was receiving HAART, she had been suffering from gastritis with severe vomiting from four months post-partum. This, in combination with prolonged fasting for religious reasons, made her adherence and drug absorption questionable. Finally, while hospitalized for severe vomiting, she suddenly ceased BF at five months. Her plasma
 235 VL result at six months postpartum showed a VL of 1600 copies/ml.

Overall, by nine months of age, seven(3.1%) children had died in the BF group and seventeen(5.6%) in the FF group. For the 22 infants who died before 9 months of age and were HIV-negative at birth, a negative PCR result was available for all of them by 3

months prior to death. The nine-month cumulative probability of death for the BF group
240 was 3.3% (95%CI 1.6-6.9%) and 5.7% (95%CI 3.6-9.2%) for the FF group, with no
statistically significant difference (log-rank test, P=0.20).

Among the 532 exposed liveborn children, 29 were HIV-1 infected or dead at nine month
of age. As shown in figure 2, the nine-month cumulative HIV-free survival was 95%
(95%CI 91-97%) in the BF group and 94% (95%CI 91-96%) in the FF group (log-rank test,
245 P=0.66).

After adjustment for potential confounders in the adjusted analysis, no significant
difference in HIV-free survival was seen between the two intervention groups, with an
adjusted HR of 1.2 (95%CI 0.5-2.9%) for BF versus FF (Table 2). The only statistically
significant factors retained were maternal CD4 cell count below 350/ μ L and birth weight
250 below 2.5 kg. If LTFU was considered as dead/infected in a sensitivity analysis, an adjusted
HR of 1.9 (95%CI 0.9-4.0%) for BF compared to FF was found (data not shown).

DISCUSSION

This is the first study reporting the field efficacy of two concomitant PMTCT interventions to
255 reduce postnatal transmission of HIV. Whereas FF has been the recommended option in developed
countries, this intervention is not feasible for many African women and carries a higher risk of
morbidity and mortality in resource-limited settings that needs to be balanced against its benefits
in preventing postnatal transmission. With the antiretroviral era in Africa since 2004, providing
HAART to women while BF is another conceivable option, offering a culturally appropriate
260 alternative. In our study, following a backbone of maternal HAART according to 2006 WHO
criteria[25], both postnatal approaches were found to be safe and effective, with similar nine-
month HIV-free survival of about 95%. The overall nine-month transmission rate was about 1.3%,
one of the lowest MTCT rate ever reported from low-income countries[29] and similar to those
reported from industrialized countries. We attribute this strong effect to the combination of starting
265 HAART prior to delivery, antiretroviral prophylaxis to the newborn and continued HAART for six
months while BF.

In a meta-analysis, the risk of HIV transmission by EBF was estimated around 0.7% per child-
month of BF follow-up[6]. In other recent African studies, the lowest reported rates of
transmission with EBF by 3-6 months have varied between 1.3 % and 5.6% [2-3, 30-31]. Although
270 these studies are difficult to compare directly, our postnatal transmission rate for women BF under
HAART would suggest a significant reduction in postnatal transmission. We found only one other
published report (DREAM Program), assessing the efficacy of BF combined with maternal
HAART to reduce postnatal transmission (additional 0.8% postnatal transmission in the BF group
with HAART), but without a FF comparison group at the same period of time[2].

275 The results with FF were also encouraging, showing an overall mortality lower than in infants born
to HIV-uninfected mothers in Rwanda[32]. The total mortality of children followed in the
AMATA trial was 4.7% at 9 months, without statistically significant differences between the BF
and FF groups. This is in contrast with some studies that have shown an overall increased
mortality in FF infants and we suggest that this is because both studies (DREAM and AMATA)
280 were strongly focused on patients' counseling, education, and good quality of care and adaptation
of the feeding option to the mother's choice. These data also confirm the importance of postnatal
follow-up for exposed children, very often neglected when PCR-testing is not available, resulting
in limited access to care and information.

We chose a cohort design instead of a randomized clinical trial to avoid the ethical problems
285 associated with a fixed allocation of the infant feeding practices[33]. In addition, this design
helped to assess the mother's choice of feeding method with FF with a close follow-up and
education for the preparation of milk. We believe this was a key factor in encouraging good
adherence[34]. To be able to offer women a culturally acceptable method of feeding, that matched
HIV transmission rates using FF, resulted in very important public health implications.

290 This study had several limitations. First, while adjusting for the cohort design our findings
remained essentially unchanged in multivariate analysis, residual confounding may still be
possible. Second, these outcomes were obtained within a specific study research setting with high
quality of care and follow-up. Consequently, these findings could not be generalized to the country
level. Third, even though the overall tolerance of HAART was very good in this study, toxicity of
295 HAART could be problematic in settings with fewer resources for follow-up.
Finally, this study did not have the power to detect small differences in postnatal HIV-1 infection
or mortality between the two approaches.

There are some public health caveats, as well. In most low-income countries, access to HAART services is still limited and particularly challenging for pregnant women during the last trimester of pregnancy. Even if accessible everywhere, cost implications of dissemination of this PMTCT model will have to be considered in each country. There is also the potential of an increased risk of infection with resistant viruses for those newborns infected while breastfed from mothers taking HAART[35]. This issue may become less problematic now since, based on a recent pediatric study, WHO currently recommends to treat all young HIV infected children with protease inhibitors in case of recent exposure to NVP[36-37].

Several relevant questions remain to be addressed. How will mixed feeding affect the postnatal transmission rate, even if HAART is taken? If HAART does protect against transmission during mixed feeding, then could HAART be continued for longer periods (e.g. up to 1 year) or during all the BF period? It also remains to be seen whether sufficient levels of adherence to prophylactic HAART can be achieved to avoid emergence of drug-resistance, especially when HAART is given for a longer period.

There may be several alternatives to replacement feedings such as diluted, boiled cow's milk or heated expressed breast milk[38] that might be more easily implemented in remote places where provision of HAART or FF can be problematic.

We conclude that BF when combined with maternal HAART can be associated with a minimal risk of postnatal transmission, similar to the FF one in our cohort, and with HIV transmission rates as low as those in high-income countries. A key implication of this study is that women can be offered a choice in infant feeding options, both of which could be safe and effective, given regular postnatal follow-up and counseling. This information would be useful in guiding

recommendations on the safest and best infant feeding modalities according to the different African contexts combined with the full spectrum of antiretroviral strategies, including ART for those in need.

325

Acknowledgments:

We thank all families of children enrolled in the study. We appreciated the constant collaboration of Ministry of health of Rwanda. We thank Joseph Viankandondera for his advice and for sharing with us his valuable experience in PMTCT clinical trials in Rwanda. We also thank Tony Reid for reviewing the manuscript in detail.
