O'Callaghan, M.D., Pierre Clerson, M.D., Robert Giroto, M.D., Frederic Galacteros, M.D., and Gerald Simonneau, M.D.

ABSTRACT

BACKGROUND

The prevalence and characteristics of pulmonary hypertension in adults with sickle cell disease have not been clearly established.

METHODS

In this prospective study, we evaluated 398 outpatients with sickle cell disease (mean age, 34 years) at referral centers in France. All patients underwent Doppler echocardiography, with measurement of tricuspid-valve regurgitant jet velocity. Right heart catheterization was performed in 96 patients in whom pulmonary hypertension was suspected on the basis of a tricuspid regurgitant jet velocity of at least 2.5 m per second. Pulmonary hypertension was defined as a mean pulmonary arterial pressure of at least 25 mm Hg.

RESULTS

The prevalence of a tricuspid regurgitant jet velocity of at least 2.5 m per second was 27%. In contrast, the prevalence of pulmonary hypertension as confirmed on catheterization was 6%. The positive predictive value of echocardiography for the detection of pulmonary hypertension was 25%. Among the 24 patients with confirmed pulmonary hypertension, the pulmonary-capillary wedge pressure was 15 mm Hg or less (indicating precapillary pulmonary hypertension) in 11 patients. Patients with confirmed pulmonary hypertension were older and had poorer functional capacity and higher levels of N-terminal pro-brain natriuretic peptide than other patients. In contrast, patients who had a tricuspid regurgitant jet velocity of at least 2.5 m per second without pulmonary hypertension and patients with a tricuspid regurgitant jet velocity of less than 2.5 m per second had similar clinical characteristics.

CONCLUSIONS

In this study of adults with sickle cell disease, the prevalence of pulmonary hypertension as confirmed on right heart catheterization was 6%. Echocardiographic evaluation alone had a low positive predictive value for pulmonary hypertension. IN SEVERAL STUDIES, PULMONARY HYPERTENSION, particularly pulmonary arterial hypertension, has been reported as a frequent complication of sickle cell disease.¹⁻⁴ Pulmonary arterial hypertension is characterized by the presence of precapillary pulmonary hypertension in the absence of left-sided heart disease, lung disease, or chronic thromboembolism. On histopathological analysis, pulmonary arterial hypertension is characterized by the proliferation of medial smooth-muscle cells and endothelial cells in the small pulmonary arteries.⁵ Pulmonary arterial hypertension may be idiopathic, heritable, or associated with other disorders, such as connective tissue diseases and congenital heart disease.⁶ In the updated classification of pulmonary hypertension, sickle cell disease appears as a separate entity in the subgroup of cases of pulmonary arterial hypertension associated with identified diseases.⁶⁻⁸

In recent studies involving adults with sickle cell disease, the prevalence of pulmonary hypertension (as defined by a tricuspid-valve regurgitant jet velocity of at least 2.5 m per second on Doppler echocardiography) has been as high as 30%.⁹⁻¹² However, in these studies, the diagnosis of pulmonary hypertension was not systematically confirmed on right heart catheterization, a procedure that is recommended in international guidelines as the standard of care.^{7,8,13} In screening programs for pulmonary hypertension in high-risk populations, the use of a definition of pulmonary hypertension that is based on the results of echocardiography alone results in a substantial number of false positive diagnoses that are not confirmed on right heart catheterization.¹⁴⁻¹⁶ Hence, invasive hemodynamic assessment is necessary to accurately diagnose pulmonary hypertension. In some studies involving patients with sickle cell disease, a tricuspid regurgitant jet velocity of at least 2.5 m per second independently predicted an increased risk of death.⁹⁻¹¹ However, the proportion of these patients with an abnormally high mean pulmonary arterial pressure is unknown. The use of right heart catheterization also makes it possible to distinguish between precapillary pulmonary hypertension, which is mainly caused by pulmonary arterial hypertension, and postcapillary pulmonary hypertension, which is associated with left-sided heart disease.^{4,6}

The objective of this study was to determine the prevalence of pulmonary hypertension, as assessed on right heart catheterization, in adults

with sickle cell disease in whom the disorder was suspected on the basis of Doppler echocardiography. We also sought to categorize pulmonary hypertension according to its cause.

METHODS

STUDY DESIGN

This prospective, multicenter study was performed in collaboration with three French referral centers for sickle cell disease and the National Reference Center for Pulmonary Hypertension. The study protocol was approved by the ethics committee at each participating center. The study was funded by the French Ministry of Health and the Delegation for Clinical Research of the Assistance Publique-Hôpitaux de Paris. The sponsors had no role in the design or conduct of the study. Data were collected by investigators at each study center.

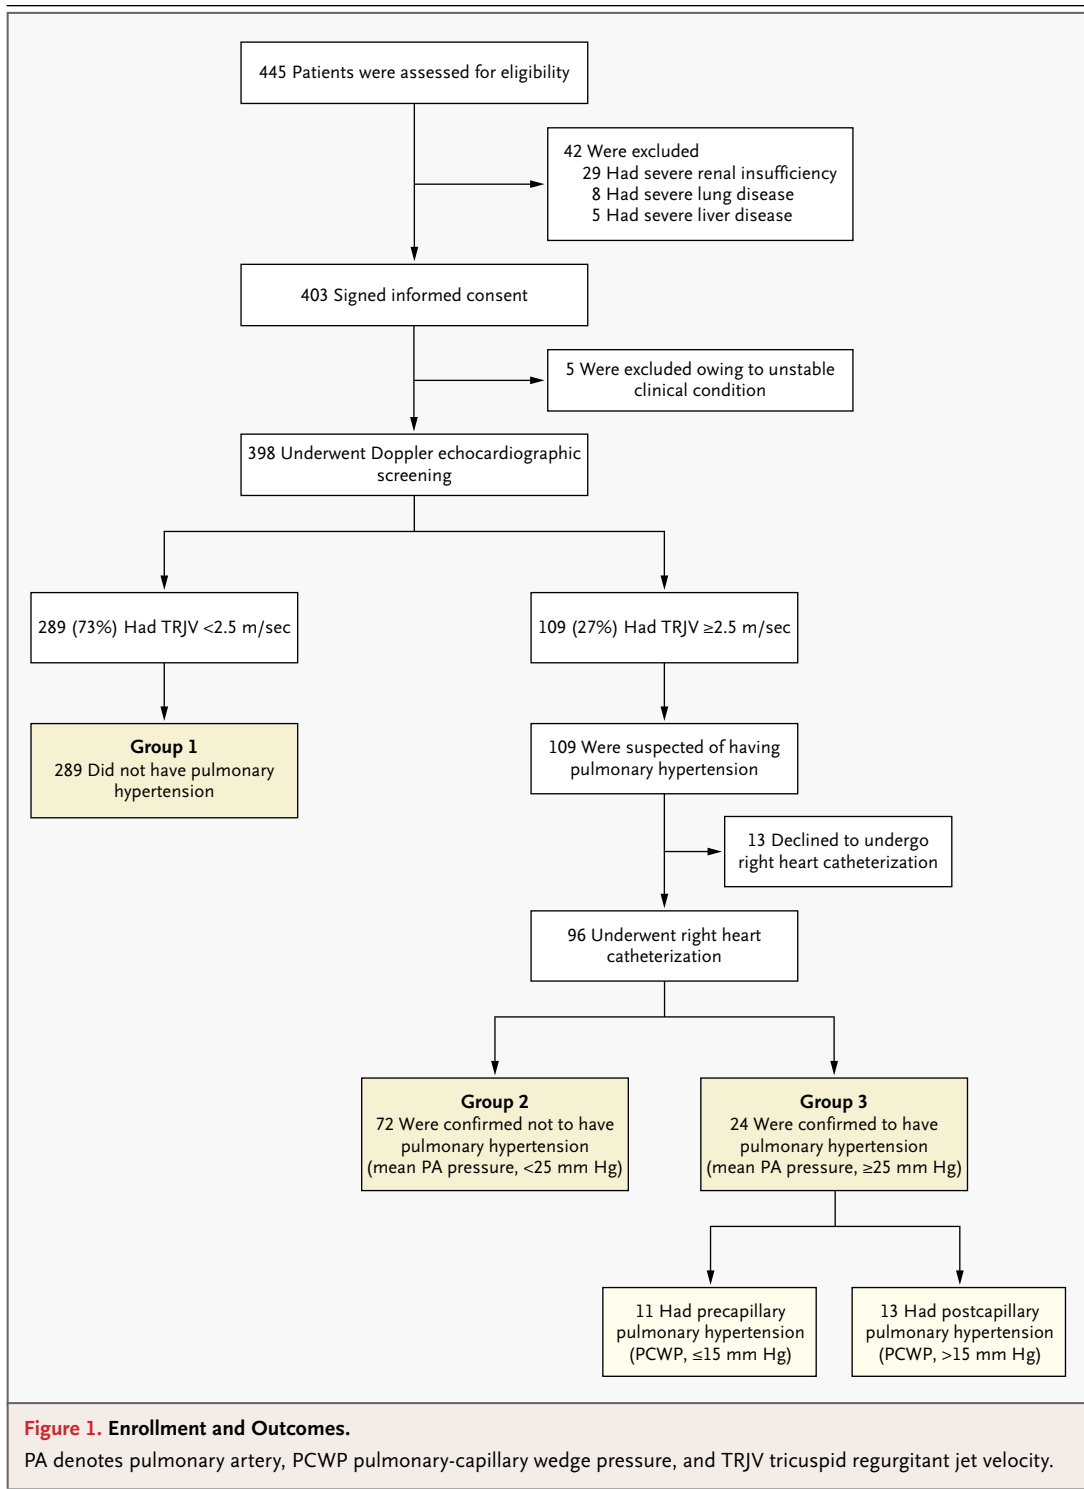

STUDY PATIENTS

Patients with sickle cell disease who were 18 years of age or older were recruited from the three referral centers. All patients were homozygous for hemoglobin S or had $S\beta^0$ thalassemia. Only outpatients in stable condition were included. Exclusion criteria were severe renal insufficiency, severe liver disease, and chronic restrictive lung disease (Fig. 1). All patients provided written informed consent. Details regarding the selection and evaluation of patients are provided in the Supplementary Appendix, available with the full text of this article at NEJM.org.

ECHOCARDIOGRAPHY AND RIGHT HEART CATHETERIZATION

We performed transthoracic echocardiography in all patients as a screening test for pulmonary hypertension.¹⁷⁻¹⁹ We used continuous-wave Doppler sampling of the peak tricuspid-valve regurgitant jet velocity to calculate the pulmonary arterial systolic pressure, as described previously.²⁰⁻²² (For details, see the Supplementary Appendix.) We then performed right heart catheterization in all patients with a tricuspid regurgitant jet velocity of at least 2.5 m per second.

On the basis of the results of echocardiography and right heart catheterization, we classified patients into three groups (Fig. 1). Patients in group 1 had either a tricuspid regurgitant jet velocity of less than 2.5 m per second or a tricuspid regurgitant jet velocity that could not be measured, without other echocardiographic signs of

pulmonary hypertension or a decrease in the diffusion capacity for carbon monoxide corrected for alveolar volume. Patients in group 2 had a tricuspid regurgitant jet velocity of at least 2.5 m per second without confirmed pulmonary hypertension on catheterization (mean pulmonary arterial pressure, <25 mm Hg). Patients in group 3 had a tricuspid regurgitant jet velocity of at least 2.5 m per second with confirmed pulmonary hypertension (mean pulmonary arterial pressure,

≥25 mm Hg). Patients in group 3 were further classified as having either precapillary pulmonary hypertension (pulmonary-capillary wedge pressure, ≤15 mm Hg) or postcapillary pulmonary hypertension (pulmonary-capillary wedge pressure, >15 mm Hg).⁶

FOLLOW-UP

We performed prospective follow-up evaluations with scheduled annual appointments with physicians for 3 years. For patients who died during follow-up, the date and cause of death were documented.

STATISTICAL ANALYSIS

We used Pearson's correlation coefficient to quantify the correlation between the estimation of systolic pulmonary arterial pressure on echocardiography and the measurement on catheterization. For intergroup comparisons, we used analysis of variance, Student's *t*-test, or the Wilcoxon test for continuous variables, depending on the number of groups for comparison and on the normality of the distribution. For categorical data, we used the chi-square test or Fisher's exact test, depending on the expected number of patients in each cell. To adjust for multiple comparisons, we performed post hoc Bonferroni tests for continuous variables. The type I error risk was partitioned for categorical variables (with a threshold of 0.025 for each comparison). For exploratory purposes, we performed a nonparametric classification and regression tree analysis²³ to evaluate the use of the 6-minute walk distance, the level of N-terminal pro-brain natriuretic peptide (NT-proBNP), and the tricuspid regurgitant jet velocity as a means of selecting patients for right heart catheterization (for details, see the Supplementary Appendix). A *P* value of less than 0.05 was considered to indicate statistical significance for all tests other than the multiple-comparisons analysis.

RESULTS

STUDY PATIENTS

From February 2007 through March 2009, we evaluated 445 patients who met the predefined inclusion criteria (Fig. 1). Of these patients, 42 were excluded because of serious coexisting illnesses, and the remaining 403 patients consented to participate in the trial; 5 patients were subsequently excluded because of an unstable clinical condition. The remaining 398 patients underwent Doppler

echocardiographic screening. Thirteen patients who were scheduled to undergo catheterization declined to participate. The baseline characteristics of the remaining 385 patients who were evaluated according to the study protocol are shown in Table 1. All 403 patients who provided consent were included in the follow-up analysis. The mean (±SD) follow-up period was 26±6 months and was similar for the three subgroups of patients.

PREVALENCE OF PULMONARY HYPERTENSION

Among the 398 patients who underwent echocardiography, 109 (27%) had a peak tricuspid regurgitant jet velocity of at least 2.5 m per second (Fig. 1). Among the 96 patients who then underwent catheterization, 24 (25%) had confirmed pulmonary hypertension. There was a significant correlation between the estimation of pulmonary arterial systolic pressure on echocardiography and measurement during catheterization (Fig. 2). However, the strength of this correlation was only moderate, as reflected in the correlation coefficient ($r=0.645$).

CHARACTERISTICS OF THE PATIENTS

The characteristics of patients according to subgroup (as defined in the Methods section) are shown in Table 2. Patients in group 1 and group 2 were similar with respect to the frequency of complications of sickle cell disease and factors reflecting the presence of hemolysis. Functional characteristics (including the New York Heart Association [NYHA] functional class and the 6-minute walk distance) and NT-proBNP levels were also similar in the two groups. However, patients in group 2 were significantly older and had a higher serum creatinine level than those in group 1.

Patients in group 3 (i.e., those with pulmonary hypertension, as confirmed on catheterization) differed markedly from patients without pulmonary hypertension. As compared with patients in groups 1 and 2, those in group 3 were significantly older and had significantly higher levels of lactate dehydrogenase and aspartate aminotransferase. In addition, the 24 patients with confirmed pulmonary hypertension also had a highly significant reduction in the 6-minute walk distance, a worse NYHA functional class, and a significantly increased NT-proBNP level, as compared with the other patients. The patients with pulmonary hypertension also had an increased frequency of leg ulcers, but there was no signifi-

* Plus-minus values are means \pm SD. Shown are the baseline characteristics of the patients who were evaluated according to the study protocol. The body-mass index is the weight in kilograms divided by the square of the height in meters. To convert the values for blood urea nitrogen to millimoles per liter, multiply by 0.357. The creatinine clearance was determined with the use of the Cockcroft formula. To convert the values for creatinine to micromoles per liter, multiply by 88.4. To convert the values for bilirubin to micromoles per liter, multiply by 17.1. ULN denotes upper limit of the normal range.

[†] Vaso-occlusive crisis was defined as pain related to sickle cell disease that required consultation at the emergency department or hospitalization.

cant difference in the incidence of other disease complications.

Hemodynamic findings in the 96 patients who underwent catheterization are shown in Table 3.

The 24 patients with confirmed pulmonary hypertension (group 3) had a higher tricuspid regurgitant jet velocity and significantly higher pulmonary arterial systolic and diastolic pressures on

catheterization than the 72 patients without confirmed pulmonary hypertension (group 2). Cardiac output was increased in both groups. Pulmonary vascular-resistance levels were significantly lower in group 2 than in group 3.

According to the prespecified definitions, 11 patients had precapillary pulmonary hypertension, and 13 patients had postcapillary pulmonary hypertension. The severity of pulmonary hypertension in patients with precapillary pulmonary hypertension was usually mild or moderate, with a high cardiac output. Only 6 of the 11 patients with precapillary pulmonary hypertension had a pulmonary vascular resistance of $160 \text{ dyn}\cdot\text{sec}\cdot\text{cm}^{-5}$ or higher, the classic criterion for pulmonary arterial hypertension.²⁴

ASSESSMENT OF ECHOCARDIOGRAPHY AS A SCREENING TEST

With a peak tricuspid regurgitant jet velocity of at least 2.5 m per second as a cutoff value for the selection of patients for catheterization, the positive predictive value of echocardiography for the detection of pulmonary hypertension was 25% (Fig. 1A in the Supplementary Appendix). In light of the updated guidelines for the use of echocardiography in screening for pulmonary hypertension,²⁵ we retrospectively analyzed the performance of a cutoff value for a tricuspid regurgitant jet velocity of at least 2.9 m per second for the selection of patients for catheterization. On the basis of this higher cutoff value, the number of catheterizations would have been reduced from 96 to 22, and the positive predictive value would have been increased from 25% to 64% (Fig. 1B in the Supplementary Appendix). However, with this higher threshold value, the false negative rate would have been at least 42%.

We performed an exploratory analysis that used a combination of the tricuspid regurgitant jet velocity, the NT-proBNP level, and the 6-minute walk distance to select patients for catheterization (for details, see the Supplementary Appendix). For this analysis, test characteristics were determined on the assumption that patients with a tricuspid regurgitant jet velocity of 2.9 m or more per second or with a tricuspid regurgitant velocity between 2.5 and 2.8 m per second plus either an NT-proBNP level of at least 164.5 pg per milliliter or a 6-minute walk distance of less than 333 m would undergo catheterization. On the basis of this approach, the positive predictive value was 62%, and the false negative rate was at least 7%.

Figure 2. Correlation between Pulmonary Arterial Systolic Pressure as Estimated on Doppler Echocardiography and as Measured on Right Heart Catheterization.

Shown are data points for all 96 patients who underwent right heart catheterization. However, some patients had identical results, so data points for these patients are superimposed. The dashed line indicates the line of identity.

ADVERSE EVENTS

Three episodes of vasoocclusive crisis occurred in three patients shortly after catheterization, necessitating brief hospitalizations. There were no permanent sequelae related to these events.

During follow-up, 6 of 403 patients (2%) died. Four of the 6 deaths occurred in association with a vasoocclusive crisis and acute chest syndrome. Of the patients who died, 1 was in group 1, 1 was in group 2, 3 were in group 3, and 1 was in the group of 13 patients with a tricuspid regurgitant velocity of at least 2.5 m per second who declined to undergo right heart catheterization. Details regarding these deaths are provided in the Supplementary Appendix.

DISCUSSION

In this study of adults with sickle cell disease, the prevalence of a tricuspid regurgitant jet velocity of at least 2.5 m per second on echocardiography was 27%, a rate consistent with those in other studies.⁹⁻¹² In contrast, the prevalence of pulmonary hypertension that was confirmed on right heart catheterization was only 6%. Approximately half the patients with confirmed pulmonary hy-

|| The NT-proBNP level was evaluated in 275 patients.

pertension had precapillary pulmonary hypertension. If we had included the 47 patients with severe end-organ damage or clinical instability who underwent initial screening (Fig. 1), the prevalence of pulmonary hypertension might have been higher. Given the high prevalence of sickle cell disease in many regions, this complication may affect a large worldwide population.

The correlation between pulmonary arterial pressure as estimated on echocardiography and as

measured on right heart catheterization was only moderately good in our study. When a threshold tricuspid regurgitant jet velocity of 2.5 m per second was used to define pulmonary hypertension, the positive predictive value of echocardiography was only 25%. If pulmonary hypertension had been defined at a higher threshold, a tricuspid regurgitant jet velocity of 2.9 m per second, the positive predictive value of echocardiography would have improved, but several patients with

* Patients in group 2 had a tricuspid regurgitant jet velocity of at least 2.5 m per second without confirmed pulmonary hypertension on right heart catheterization. Patients in group 3 had a tricuspid regurgitant jet velocity of at least 2.5 m per second and confirmed pulmonary hypertension on right heart catheterization. Data from patients in group 1 with a tricuspid regurgitant jet velocity of less than 2.5 m per second are not listed because they did not undergo right heart catheterization. NT-proBNP denotes N-terminal pro-brain natriuretic peptide.

† P values were calculated with the use of Student's t-test, except for the comparison of NT-proBNP levels, which was performed with the use of the Wilcoxon test, and the comparison of the functional New York Heart Association class, which was performed with the use of Fisher's exact test.

‡ Precapillary pulmonary hypertension is defined as a mean pulmonary arterial pressure of at least 25 mm Hg and a pulmonary-capillary wedge pressure of 15 mm Hg or less. Postcapillary pulmonary hypertension is defined as a mean pulmonary arterial pressure of at least 25 mm Hg and a pulmonary-capillary wedge pressure of more than 15 mm Hg. Chronic thromboembolic pulmonary hypertension was ruled out on the basis of normal or nearly normal results on a ventilation-perfusion lung scan in all patients with precapillary pulmonary hypertension.

§ Pulmonary vascular resistance was calculated as [(mean pulmonary arterial pressure – pulmonary-capillary wedge pressure) ÷ cardiac output] × 80.

pulmonary hypertension would not have been detected with such a threshold. We could not determine the false negative rate from our findings, since patients with a tricuspid regurgitant velocity of less than 2.5 m per second did not undergo right heart catheterization and some cases of pulmonary hypertension may not have been identified. Nonetheless, the use of the tricuspid regurgitant jet velocity on echocardiography as a single screening tool for the selection of patients for right heart catheterization does not appear to be ideal, whatever threshold is selected. There may be several reasons for the discrepancy between these two methods, including the imprecision of the echocardiographic measurement, inherent

physiological variations in pulmonary hemodynamics, and the interval between echocardiography and catheterization (a median delay of 15 days).

As an alternative approach, we conducted an exploratory analysis to evaluate the use of tricuspid regurgitant velocity on echocardiography together with the NT-proBNP level and the 6-minute walk distance to select patients for right heart catheterization. In the resulting algorithm, right heart catheterization was recommended if the patient had a tricuspid regurgitant velocity of 2.9 m or more per second; for patients with a tricuspid regurgitant velocity between 2.5 and 2.8 m per second, right heart catheterization was recommended if the NT-proBNP level was at least

164.5 pg per milliliter or the 6-minute walk distance was less than 333 m. This approach would have been more accurate in selecting patients for right heart catheterization than using a tricuspid regurgitant velocity of 2.9 m per second alone. However, this algorithm is a provisional model derived directly from our own data. Given the limited number of patients in some of the subgroups in our study, and given the fact that this algorithm has not been validated in other patients with sickle cell disease, it cannot be considered suitable for general clinical application.

As has previously been reported, patients with sickle cell disease and precapillary pulmonary hypertension had a less marked increase in mean pulmonary arterial pressure, higher values of cardiac output, and lower levels of pulmonary vascular resistance than did patients with idiopathic pulmonary arterial hypertension.⁴ Despite having less severe hemodynamic impairment, these patients nonetheless had a clinically significant functional limitation, as assessed according to NYHA functional class (with 45% of patients in class III or IV) and a marked decrease in the 6-minute walk distance (mean, 406 m). This poor exercise tolerance, despite only mild or moderate pulmonary hypertension, is probably multifactorial. Anemia, intrinsic cardiac disease, pulmonary vascular disease with oxygen desaturation, and musculoskeletal problems may all contribute to worsening of functional status.

The role of hemolysis in the pathogenesis of pulmonary hypertension in patients with sickle cell disease remains controversial.²⁶ In our study, data regarding biologic markers of hemolysis were discordant. Hemoglobin and indirect bilirubin levels were similar in patients with confirmed pulmonary hypertension and in those without pulmonary hypertension. In contrast, we observed in patients with confirmed pulmonary hypertension

significantly increased lactate dehydrogenase and aspartate aminotransferase levels, which may also be influenced by liver dysfunction. Further studies are needed to clarify the role of hemolysis in pulmonary hypertension in patients with sickle cell disease.

In our study, the overall rate of death was 2%, which was significantly lower than the rate of 5.3% reported in a previous study by Gladwin et al.,⁹ involving adults with sickle cell disease in the United States, despite similar mean follow-up periods in the two studies (26 months and 18 months, respectively). Such a discrepancy in mortality may be partially explained by our exclusion of patients with severe lung or liver disease or renal insufficiency. The French and U.S. study populations also differed with respect to the frequency of vascular complications, which occurred less often in our patients. Lastly, patients in the U.S. study were recruited through community outreach programs and advertising campaigns, whereas our patients were recruited from referral centers.

In conclusion, in a study of adult outpatients with stable sickle cell disease, we found that the prevalence of pulmonary hypertension, as detected on initial echocardiographic screening and confirmed by right heart catheterization, was 6%. Echocardiographic evaluation alone with the use of the tricuspid regurgitant velocity as a threshold criterion had a low positive predictive value for pulmonary hypertension. The optimal approach for screening such patients for right heart catheterization remains uncertain.
