Abstract

Background: One possible risk marker of later internalising symptoms is poor sleep, which is a problem for up to 40% of children. The present study investigated whether prior sleep problems could predict internalising symptoms over a period of 18 years of follow-up.

Methods: The study sample included 1,503 French young adults from the TEMPO cohort (mean age=28.8±3.6 years) whose parents participate in the GAZEL cohort study. All TEMPO participants previously took part in a study of children's mental health and behaviour in 1991 (mean age=10.3±3.6 years) and 1999 (mean age=18.8±3.6 years). Sleep problems and internalising symptoms (depression, anxiety, somatic complaints) were assessed three times (1991, 1999, 2009) using the Achenbach System of Empirically Based Assessment (ASEBA) questionnaire. The association between sleep problems in 1991 and trajectories of internalising problems from 1991 to 2009 was tested in a multinomial logistic regression framework, controlling for sex, age, baseline temperament, behavioural problems and stressful life events, as well as family income, and parental history of depression.

Results: We identified four trajectories of internalising symptoms: *high-persistent* (2.5%), *high-decreasing* (11.4%), *low-increasing* (11.6%), and *low-persistent* (74.5%). After controlling for covariates, compared to participants who did not have sleep problems in 1991, those who did were 4.51 times (95% CI = 1.54 – 13.19, P=.006) more likely to have *high-persistent* internalising symptoms and 3.69 times (95% CI = 2.00 – 6.82, P<.001) more likely to have *high-decreasing* internalising symptoms over the 18-year follow-up.

Limitations: Sleep problems and internalising symptoms were based on self-report questions, results should be interpreted with due caution.

Conclusions: Sleep problems early in life are associated with an increased likelihood of internalising symptoms that persist from childhood to adulthood.

Keywords: Sleep problems, depressive and anxiety symptoms, longitudinal study, epidemiology

1. Introduction

Internalising problems, defined as a spectrum of symptoms of depression, anxiety, withdrawal, and somatic complaints (Achenbach et al., 1989), affect up to 40% of youth (Crawford et al., 2001). In up to 50% of cases, these symptoms persist over time, affecting quality of life, interpersonal relationships, as well as academic and occupational attainment (Bongers et al., 2003). It is therefore important to identify youth at risk of persistent internalising symptoms in order to address their mental health needs early on and potentially prevent a long-term cycle of poor outcomes.

One possible risk marker of later internalising symptoms is poor sleep, which is a problem for up to 40% of children (Mindell et al., 1999). Although sleep problems are sometimes considered a sign of anxiety and depression (Ostberg & Hagelin, 2011), research shows that they often precede the occurrence of other manifestations of psychological difficulties (such as excessive worry, unexplained somatic symptoms, sadness or social withdrawal). Sleep problems are associated with increased risk of internalising symptoms (particularly anxiety) in toddlers (Jansen et al., 2011), children (Pesonen et al., 2010), adolescents (Gregory & O'Connor, 2002), and adults (Gregory et al., 2005). For instance, a longitudinal study which followed 4-19 year olds over a period of 14 years, found that various types of sleep problems, as reported by the parents using the Child Behavioural Checklist (CBCL) (e.g., “decreased sleep”, “overtiredness”, and “trouble sleeping”) predicted later depression and anxiety (Gregory et al., 2008). However, to our knowledge, the relationship between sleep problems early on and trajectories of psychological difficulties has not been studied. In the present study, we examined the relationship between sleep problems measured between 4 and 16 years of age, and internalising symptoms over an 18 year follow-up period, accounting for factors which could explain this association (sex (Hankin et al., 2007),

temperament (Touchette et al., 2005), behavioural difficulties (Silk et al., 2003), stressful life events (Eley & Stevenson, 2000), family socioeconomic position (Arber et al., 2009), (Lorant et al., 2003; Melchior et al., 2011), and parental depression (Swanson et al., 2010).

2. Methods

2.1 Study population

The TEMPO (Trajectoires Epidémiologiques en Population) cohort study, based in France, was set up in 2009 to follow-up young adults (22-35 years) who had taken part in a study of children's psychological problems and access to mental health care in 1991. The original sample of children surveyed in 1991 (GAZEL Youth study, n=2,498) was selected among 4-16 year olds whose parents participate in the GAZEL cohort study which follows 20,624 employees of a large French public-sector utility company by yearly mailed questionnaire since 1989 (Goldberg et al., 2007). The 1991 sample of children was selected to match key characteristics of children in France (number of children per family and occupational grade of head of household) (Fombonne & Vermeersch, 1997a, 1997b). Data on participating children were collected via parental reports. In 1999, data were collected by parental reports (n=1,268) and youth self-reports (n=1,148).

In 2009, all living parents of children who took part in the GAZEL Youth Study in 1991 received a letter asking them to forward the TEMPO study questionnaire to their son/daughter. Between 1991 and 2009, 16 participants died and 4 were too ill or disabled to answer. The overall response rate to the TEMPO questionnaire was 44.5% (n=1,103), which is comparable to response rates of other mental health surveys in France (Alonso et al., 2004). Leading reasons for non-participation were non-transmission of the questionnaire by the parent (34.4%) or the youth's lack of interest (28.5%). Compared to 2009 respondents, non-

respondents were older, more likely to have parents who were divorced, and had low socioeconomic background but did not vary with regard to their parents or their own overall psychological characteristics. The TEMPO study was reviewed and approved by an ethical board (CCTIRS: Comité Consultatif sur le Traitement des Informations pour la Recherche en Santé) and France's national committee for data protection (CNIL: Commission Nationale Informatique et Liberté).

2.2. Outcome measures

Participants' internalising symptoms were measured three times (1991, 1999, 2009) using the Achenbach System of Empirically Based Assessment (ASEBA). This widely used instrument comprises 118 items which assess behaviour (internalising and externalising symptoms) over a six-month period (Achenbach, 1991). This questionnaire has previously been validated in France (Fombonne, 1991); (Stanger et al., 1994). As suggested by Gregory et al. (Gregory et al., 2011), we used the most rigorous CBCL sleep item: "Does your child have sleep problems?" which has been shown to correlate with sleep latency assessed both by diary ($P=.008$) and actigraphic measures ($P=.029$). We considered sleep problems to be present when the parents reported them "sometimes" or "often" (vs. never). In additional analyses, we used a stricter cut-off, comparing individuals who had sleep problems "often" to those who had sleep problems "sometimes" or "never". Internalising symptoms (i.e. depressive symptoms, anxiety, withdrawal, and somatic complaints) were assessed by parental reports (1991: $n=32$ items), by parental and youth self-reports combined (1999: $n=31$ items) and by young adult self-reports (2009: $n=43$ items). Each time, we excluded "sleep problems" from the items included to construct the internalising symptoms score. Internalising symptoms scores had high internal consistency at all three measurement points: Cronbach's alphas as follows: 1991=0.83, 1999=0.88, and 2009=0.93. To estimate

trajectories of internalising symptoms, we used continuous scores. Additionally, we also dichotomised internalising symptoms to identify participants with clinically significant symptoms levels, using the 85th percentile score suggested by Amone-P'Olak et al.(Amone-P'Olak et al., 2009).

2.3. Description of covariates

In the present study, we controlled for the following covariates:

- 1) *Sex* (male vs. female);
- 2) *Age* (studied as a continuous variable);
- 3) *Childhood unstable temperament*, reported retrospectively for age 7-10 years by parents at time 2 using the French version of the Emotionality Activity Sociability (EAS) questionnaire(Gasman et al., 2002). Unstable temperament score was defined based on answers to five items: "Cried easily?", "Was too sensitive?", "Got excited over nothing?", "Was easily upset?", and "Reacted strongly when upset?". This score was then standardized to a mean of 0 and standard deviation of 1.
- 4) *Initial externalizing problems* (studied as a continuous variable) comprising aggressive and rule-breaking behaviours of the ASEBA questionnaire in 1991;
- 5) *Stressful life events* were measured by a combination of experiences and situations reported in 1991 (i.e., school difficulties, parental stress, childhood illness, childhood social isolation, illness of a close family member/friend, move, parental quarrels, death of a close family member/friend, parental unemployment/financial problems, parental absence from home) and parental divorce prior to age 18 as assessed based on parents' reports in the yearly GAZEL study questionnaire. We summed all stressful life events and parental divorce and studied a total score ranging from 0 to 11;

6) *Family socio-economic status* was assessed by parent-reported family income in 1989 (dichotomized at the median value of 1,981 €/month) (INSEE, 2009)

7) *Parental depression* was assessed using two sources of information: 1) ≥ 2 self-reports of depression in the yearly GAZEL study questionnaire (1989-2009), and 2) TEMPO participants' 2009 reports of their parents' lifetime experience of depression (yes vs. no) on the National Institute of Health-Family Inventory for Genetic Studies (NIH-FIGS) questionnaire (Maxwell, 1992).

2.4. Statistical Analyses

The analyses were based on 1,503 TEMPO participants who took part in at least two out of three study assessments (1991, 1999, 2009). First, we tested age and sex-adjusted concomitant associations between sleep problems and clinically significant internalising difficulties. Logistic regression models were used to test whether sleep problems in 1991 predicted the emergence of later internalising difficulties after adjusting for internalising difficulties in 1991 and the aforementioned covariates.

Next, we identified trajectories of internalising difficulties from 1991 to 2009 using a semiparametric modeling method (Nagin, 2005) implemented in SAS® (SAS Institute Inc., Cary, NC, PROC TRAJ). Based on the maximum Bayesian information criterion (BIC) the model identified four trajectories as the best fit to the data. Each individual was assigned to a specific trajectory based on a posterior probability of belonging to that group. We tested univariate associations between both sleep problems in 1991 and trajectories of internalising symptoms and all potential covariates using chi-square tests (for categorical variables), and t-tests or ANOVAs (for continuous variables).

Finally, a multinomial multivariate regression was performed to assess the association between prior sleep problems and trajectories of internalising symptoms adjusting for participants' age, sex, and all covariates associated with the presence of sleep problems in 1991 and/or trajectories of internalising symptoms ($P < 0.10$). Analyses were performed using the SPSS statistical software (version 16.0, SPSS Inc, Chicago, ILL).

3. Results

3.1 Transversal analyses between sleep and internalising problems

In the present study, 17.4% ($n=260$) of children had sleep problems in 1991, 29.9% ($n=330$) in 1999 and 34.3% ($n=364$) in 2009. Restricting the definition to frequent sleep problems, prevalences were as follows: 3.7% ($n=56$) in 1991, 7.1% ($n=78$) in 1999 and 7.5% ($n=80$) in 2009. **Table 1** shows moderate age and sex-adjusted correlations between sleep problems in 1991 and internalising problems in 1991 ($r=.18$), 1999 ($r=.17$), and no association with internalising symptoms in 2009 ($r=.03$). As shown in **Table 2**, adjusting for internalising problems in 1991 and all covariates, sleep problems in 1991 were associated with internalising problems in 1999 (OR=2.18, 95% CI=1.22 – 3.89, $P=.009$) but not in 2009 (OR=0.71, 95% CI=0.38-1.39, $P=.33$)

[Insert Tables 1 and 2 about here]

3.2 Trajectories of internalising symptoms

Figure 1 depicts trajectories of internalising symptoms between 1991 and 2009. The majority of participants (74.5%, $n=1,119$) had persistently low internalising symptoms throughout follow-up (*persistently low trajectory*). Moreover, 11.4% of participants ($n=171$) had high internalising symptoms in 1991 which decreased during follow-up (*high-decreasing trajectory*). In addition, 11.6% ($n=176$) had low levels of internalising symptoms in 1991

which increased over the course of time (*low-increasing trajectory*). Finally, 2.5% of study participants (n=37) had high levels of internalising symptoms throughout follow-up (*high-persistent trajectory*).

[Insert Figure 1 about here]

3.3. Selection of covariates

As shown in **Table 3**, sleep problems in 1991 were significantly associated with stressful life events ($P<.001$), externalizing problems ($P<.001$), an unstable temperament ($P=.001$) and parental depression ($P=.01$). Trajectories of internalising symptoms were significantly associated with participants' age ($P<.001$), sex ($P<.001$), stressful life events ($P<.001$), externalizing problems ($P<.001$), an unstable temperament ($P<.001$), and parental depression ($P<.001$), but not with family income ($P=.20$). For consistency with prior studies, family income was nevertheless controlled for.

[Insert Table 3 about here]

3.4. Sleep problems in 1991 and trajectories of internalising symptoms

We found an association between sleep problems in 1991 and trajectories of internalising symptoms ($P<.001$) and this association was statistically significant in female and male participants (respectively $P<0.001$ and $P<0.001$). Sleep problems in 1991 were more frequent in participants in the high-persistent (girls=44.8%, boys=57.1%) or high-decreasing (girls=41.4%, boys=38.6%) trajectories of internalising symptoms than in the low-increasing (girls=17.5%, boys=18.0%) and low-persistent (girls=14.0%, 11.8%) trajectories. Associations between sleep problems and internalising symptoms trajectories did not vary with sex (interaction term not statistically significant).

Multivariate multinomial regression models testing associations between sleep problems in 1991 and trajectories of internalising symptoms adjusting for all covariates are presented in **Table 4**. As expected, compared to participants with no sleep problems, those who had sleep problems in 1991 were more likely to have a high-persistent trajectory of internalising symptoms (OR=4.51, 95% CI: 1.54-13.19, P=0.006) or a high-decreasing trajectory (OR=3.69, 95% CI = 2.00 – 6.82, P<.001). We found no association between sleep problems in 1991 and a low-increasing internalising symptoms trajectory (P=.89). Additional variables associated with the high-persistent trajectory of internalising symptoms were female sex and an unstable temperament. Additional variables associated with the high-decreasing internalising symptoms trajectory were female sex, an unstable temperament, externalizing problems, and stressful life events

[Insert Figure 2 and Table 4 about here]

4. Discussion

Studying a sample of young adults drawn from the community, we found that participants who had prior sleep problems had an elevated likelihood of experiencing long-term internalising problems. After accounting for important covariates, children who had sleep problems were 4.5 times more likely to have persistently high levels of internalising symptoms into young adulthood but, 3.7 times more likely to have high levels of internalising symptoms that later decreased. This association did not appear to be sex-specific; it was equivalently observed in girls and boys.

The results of the present study corroborate the predictive link between prior sleep problems and internalising problems later in life observed in previous longitudinal studies (Gregory & O'Connor, 2002; Jansen et al., 2011). Dyssomnias, parasomnias, and short sleep duration at 18 months of age increase the risk of occurrence of depressive or anxiety

symptoms at age 3 even after taking into account pre-existing depressive or anxiety symptoms (Jansen et al., 2011). Moreover, sleep problems at age 4 predict behavioral/emotional problems in mid-adolescence (Gregory & O'Connor, 2002). However, we found no association between early sleep problems in 1991 and internalising problems in young adulthood, implying that internalising symptoms in adulthood have other determinants. In order to clarify the mechanisms underlying this association, future studies should focus on prior sleep problems measured objectively and mental health assessed later in life.

ASEBA measures symptoms present over the last 6 months (Achenbach, 1991). This suggests that the ASEBA may reflect trait as well as state expressions of psychopathology (Biederman et al., 2008). For example, individuals in the high-persistent internalising symptoms trajectory could indicate more a trait than a state of internalising symptoms compared with the other internalising symptoms trajectories. Different mechanisms could explain why prior sleep problems predict youths' internalising problems. First, this association could reflect common genetic influences, as suggested by a study of three hundred 8-year-old twin pairs (Gregory et al., 2006). Several physiological pathways through the monoaminergic system (serotonin, norepinephrine, and dopamine) and potentially the glutamatergic system (Hashimoto, 2009), (Willner, 1983) are involved in both sleep and emotional problems.. In addition, chronic stress induced by persistent sleep problems could affect the hypothalamic-pituitary-adrenal (HPA) axis (Buckley & Schatzberg, 2005) and result in an unusual pattern of cortisol secretion (Feder et al., 2004), which in turn, may have an effect on higher-order regulatory systems involved in emotional regulation. Similar HPA axis deregulations have been found in humans with depression and in prenatally stressed animals, suggesting that gestational stress could increase the risk of developing internalising problems (Weinstock, 1997). Moreover, sleep problems decrease daytime vigilance (Peters et al., 2009) which is increasingly thought to be associated

with disproportionate levels of behavioral/emotional problems (Lavigne et al., 1999; Stein et al., 2001).

Conversely, shared environmental factors seem to explain a moderate proportion of the variance in the association between sleep problems and psychological problems such as depression (Gregory et al., 2006). Particularly, inadequate parental behaviors impeding self-soothing abilities could be implicated into both sleep-wake and emotional regulatory systems (Touchette et al, 2009). Underlying child characteristics, such as temperament, might also be involved. In the present study, unstable childhood temperament was independently associated with later internalising symptoms but did not explain the association between prior sleep problems and the emergence of internalising symptoms 8 years later.

Several methodological strengths and limitations should be mentioned. We studied a longitudinal sample of community-based children for a period of 18 years where prior sleep problems were measured independently from internalising symptoms and analyses were adjusted for pre-existing individual and familial characteristics. As in many epidemiological studies, our measure of sleep was based on a single CBCL sleep item, which is well correlated with sleep latency assessed by diary and actigraphic measures (Gregory et al., 2011). As others (Gregory et al., 2005; Gregory et al., 2008), we used parental perceptions of sleep problems, which could be different from polysomnographic sleep problems. In addition, we used ASEBA scores to assess psychological difficulties, which are less specific than psychiatric diagnoses. Nevertheless, the ASEBA system has good psychometric properties (Carter et al., 2004) and has frequently been used to screen for clinically significant depressive/anxiety problems throughout the life course.

5. Conclusion

Sleep problems early in life may contribute to the development of internalising problems which persist for a significant period of life. Specifically, children with sleep problems appear vulnerable to internalising symptoms in adolescence, which sometimes persist into young adulthood. These results highlight the importance of investigating the presence of sleep problems in children, as these may be indicative of risk of long-term psychological difficulties. Future studies should explore the biological mechanisms underlying the association between sleep problems and internalising symptoms and test whether treatment of sleep problems can help contain the risk of internalising psychological difficulties later on in life.

Table 1. Concomitant and longitudinal associations between sleep problems and clinically levels of standardized internalizing problems without including sleep items in the total score at each time of measure (>85th percentile) adjusted on participants' age and sex (TEMPO cohort, 2009, n=1503).

Sleep problems ("Sometimes true/often true")	Internalizing problems (>85th percentile)		
	T1	T2	T3
T1	.25**	.17**	.03
T2		.27**	.07
T3			.33**

** Correlation is significant at the 0.01 level (2-tailed).

Table 2. Logistic regression models were used to test whether sleep problems in 1991 predicted the emergence of later internalizing difficulties after adjusting for baseline internalizing difficulties and important covariates (TEMPO cohort, 2009, n=1503).

Sleep problems ("Sometimes true/often true")	Internalizing problems (>85th percentile)			
	T2		T3	
	OR (95% CI)	P	OR (95% CI)	P
T1	2.18 (1.22 - 3.89)	.009	0.72 (0.38 - 1.39)	.33
T2			1.33 (0.79 - 2.23)	.29

OR means odds ratio. 95% CI means confidence intervals.

Experiencing stressful life events [†]	1.41	(0.99 - 2.01)	.06	1.27	(1.04 - 1.55)	.02	1.05	(0.86 - 1.29)	.63
Externalizing problems [†]	1.04	(0.97 - 1.10)	.26	1.05	(1.02 - 1.08)	.004	0.98	(0.95 - 1.02)	.31
<Median family income	1.44	(0.47 - 4.39)	.52	1.13	(0.62 - 2.06)	.70	1.36	(0.79 - 2.36)	.27

OR: odds ratio, 95% CI: confidence intervals, and †: continuous variables.

^{||} compared with trajectory of individuals who reported persistently low internalizing problems (n=1119).

[‡] Adjusted for age, sex, unstable temperament, parental history of depression, income status, experiencing stressful life events, externalizing problems, and median family income.

High-P refers to a trajectory of High-persistent internalizing symptoms; High-D refers to a trajectory of high-decreasing internalizing symptoms; Low-I refers to a trajectory of low-increasing internalizing symptoms and Low-P refers to a trajectory of low-persistent internalizing symptoms.
