Abstract

1 Glucose-6 phosphatase (G6Pase), a key enzyme of glucose homeostasis, catalyses the
2 hydrolysis of glucose-6 phosphate (G6P) to glucose and inorganic phosphate. A
3 deficiency in G6Pase activity causes type 1 glycogen storage disease (GSD-1), mainly
4 characterised by hypoglycaemia. Genetic analyses of the two forms of this rare disease
5 have shown that the G6Pase system consists of two proteins, a catalytic subunit (G6PC)
6 responsible for GSD-1a, and a G6P translocase (G6PT), responsible for GSD-1b.
7 However, since their identification, few investigations concerning their structural
8 relationship have been made.
9

10 In this study, we investigated the localisation and membrane organisation of the G6Pase
11 complex. To this aim, we developed chimera proteins by adding a fluorescent protein to
12 the C-terminal ends of both subunits. The G6PC and G6PT fluorescent chimeras were
13 both addressed to perinuclear membranes as previously suggested, but also to vesicles
14 throughout the cytoplasm. We demonstrated that both proteins strongly colocalised in
15 perinuclear membranes. Then, we studied G6PT organisation in the membrane. We
16 highlighted FRET between the labelled C and N termini of G6PT. The intramolecular
17 FRET of this G6PT chimera was 27%. The coexpression of unlabelled G6PC did not
18 modify this FRET intensity. Finally, the chimera constructs generated in this work
19 enabled us for the first time to analyze the relationship between GSD1 mutations and
20 the intracellular localisation of both G6Pase subunits. We showed that GSD1 mutations
21 did neither alter the G6PC or G6PT chimera localisation, nor the interaction between
22 G6PT termini. In conclusion, our results provide novel information on the intracellular
23 distribution and organisation of the G6Pase complex.

Glucose-6 phosphatase (G6Pase) catalyses the last enzymatic step before the release of glucose into the blood: the hydrolysis of glucose-6 phosphate (G6P) into glucose and inorganic phosphate (Pi). G6Pase activity is restricted to the liver [1], the kidney cortex [2] and the small intestine [3] and confers on these three organs the capacity to release glucose into the systemic circulation. This enzyme plays a key role in glucose homeostasis since a deficiency in G6Pase activity leads to a severe metabolic disorder mainly characterised by hypoglycaemia in the post-absorptive state: glycogen storage disease type 1 (GSD-1) [4]. From human genetic studies, GSD-1 patients have been classified in two types based on mutations of the *G6Pase catalytic subunit (g6pc)* or the *G6P translocase (g6pt)*. GSD-1a results from mutations in *g6pc* and GSD-1b from mutations in *g6pt*. Both proteins are thought to be anchored in the endoplasmic reticulum (ER) and also expressed in nuclear membranes [5]. This localisation was suggested from biochemical and histochemical studies based on phosphatase enzymatic activity [6-8]. However, no recent data based on the detection of G6Pase proteins have confirmed this intracellular localisation.

Since G6PC and G6PT are sufficient to completely account for G6Pase activity [9, 10], the current G6Pase substrate transport model proposes that the active site of G6PC is exposed to the ER lumen [11] and G6PT shuttles intracellular G6P across the ER membrane into the lumen, where it is hydrolysed. This model, based on two proteins, takes into account the kinetic characteristics of the G6Pase system. Indeed, in intact microsomal membranes (which correspond to an intact G6Pase system), G6P is specifically hydrolysed at a moderate rate and with high affinity. In solubilised ER membranes, in which catalytic activity is not dependent on substrate transport, G6Pase hydrolyses G6P at a high rate and affinity but, it decreases its substrate specificity and is therefore able to hydrolyse other sugar-6 phosphate moieties [12]. Moreover, disruption of microsomal membranes of livers from GSD-1b patients permits the recovery of normal G6Pase activity, whereas intact GSD-1b liver microsomes exhibit very low G6Pase activity [13, 14]. This set of data has suggested that G6PT is necessary for G6P transport in intact ER membranes and confers substrate specificity to the G6Pase system.

The importance of both proteins for optimal enzymatic activity has been confirmed in animal models. Using mice knocked out for *g6pc* (*g6pc*^{-/-}), Lei *et al.* have

1 suggested that a loss of *g6pc* gene expression annuls both G6P transport and hydrolysis
2 [15]. In *g6pc*^{-/-} mice, a single administration of an adenovirus containing the cDNA
3 encoding *g6pc* (AdCMV-G6PC) improved the majority of GSD-1a metabolic
4 abnormalities. The AdCMV-G6PC infusion restored 19% of normal G6Pase activity in
5 the liver and, interestingly, corrected G6P transport deficiency in hepatic microsomes of
6 *g6pc*^{-/-} mice [16]. The same authors examined microsomal G6P transport in transient
7 expression studies in COS-1 cells and have shown that G6P transport is increased in
8 cells transfected with either the *g6pc* or *g6pt* cDNA compared with mock-transfected
9 cells. Moreover, G6P transport was more efficient in cells which co-expressed both
10 genes [17]. These studies provide direct evidence that G6PT and G6PC are tightly inter-
11 dependent for global G6Pase activity.

20 Concerning their protein characteristics, neither proteins of the G6Pase system
21 have been purified to homogeneity, but their individual structures within the membrane
22 have been predicted using proteolytic digestion of tagged proteins [18, 19]. We have
23 reported that [³²P]G6PC migrates at an apparent molecular mass of 37 kDa in SDS-
24 PAGE under denaturing conditions. This is consistent with its molecular mass
25 determined by immunoblotting [20]. Using radiation inactivation analysis, Ness *et al.*
26 suggested that the molecular weight of functional G6Pase ranged around 75-100 kDa, in
27 both intact and solubilised ER membrane [21]. These observations have suggested that
28 the catalytic subunit (37 kDa) could be associated with another polypeptide through
29 disulphide bonds, and that this association could be maintained under some denaturing
30 conditions. This has raised the hypothesis that G6PT might be able to interact with
31 G6PC, resulting in the formation of a complex.

41

42 The first aim of the present study was to document the intracellular localisation
43 of G6Pase subunits. The proteins of the G6Pase complex were thus singly labelled on
44 the C or N terminus with cyan fluorescent protein (CFP) for G6PC or yellow
45 fluorescent protein (YFP) for G6PT. We also took advantage of these constructs to test
46 the hypothesis of a direct interaction between both subunits of the G6Pase enzymatic
47 system. To this purpose, we used fluorescence resonance energy transfer (FRET) with
48 CFP as the donor and YFP as the acceptor. The second aim of this work was to test a
49 putative direct interaction between the G6PT cytoplasmic termini. We thus developed a
50 G6PT protein doubly labelled on the C and N termini with CFP and YFP, respectively.
51 Using this chimera protein, we obtained further information on the structural
52 conformation of G6PT within the membrane. Finally, we studied whether the presence

2 of GSD-1 mutations affected the localisation of both G6Pase subunits and/or the
3 interaction between the C and N termini of the G6PT protein.
4

5 **2. Materials and methods**

6 *2.1 Generation of constructs*

7
8 We used pSVK3-G6PC and pSVK3-G6PT constructs which contained the
9 coding sequence for human *g6pc* (Genbank number NM 000151) and *g6pt* (Genbank
10 number Y15409) cloned at *EcoRI* and *Sal I* restriction sites (Bady and Mithieux
11 unpublished results). Chimera proteins G6PC-CFP and G6PT-YFP with fluorophores at
12 the C-terminus end were generated introducing *g6pc* and *g6pt* cDNA into pECFP-N1
13 and pEYFP-N1 vectors (Clontech) at *EcoRI* and *Sal I* restriction sites. Chimera proteins
14 CFP-G6PC and YFP-G6PT with fluorophores at the N-terminus end were generated
15 introducing *g6pc* and *g6pt* cDNA into pECFP-C1 and pEYFP-C1 vectors (Clontech) at
16 *EcoRI* and *Sal I* restriction sites. Sequences encoding stop codons avoiding correct
17 labelling were deleted by mutagenesis (QuikChange, site-directed mutagenesis kit,
18 STRATAGENE). The resulting chimera contained no additional amino acids between
19 the G6PC/G6PT and the CFP/YFP sequences (See supplemental figure 1 for amino acid
20 sequences of the chimera proteins).

30
31

32 In the case of the *CFP-G6PT-YFP* chimera protein, the DNA fragment encoding
33 G6PT-YFP fusion protein was obtained after digestion of pG6PT-YFP plasmid at *XhoI* /
34 *HpaI* restriction sites. For an easy cloning strategy, this cDNA was inserted to *XhoI* /
35 *HpaI* in pECFP-Nuc vector. This cloning strategy induced the removal of the nuclear
36 localisation signal of the simian virus large T-antigen contained in the pECFP-Nuc
37 vector and produced a chimera protein containing a linker of 13 amino acids between
38 the CFP and G6PT sequences (See supplemental figure 1).

transfection, 1 day before transfection, 100,000 cells were plated out in two-well cell culture plates (Labteck, NUNC). The complete medium was refreshed 1 h prior to transfection. Cells were transfected using the Exgen 500 reagent (Euromedex) with 200 ng of each construct. After 48 hrs of incubation, the transfection efficiency was about 60% (data not shown).

2.3 Immunoblotting and immunohistochemistry

Whole proteins extracts were prepared from cells homogenised in 10 mM HEPES, pH 7.3 by ultrasonication coupled with freeze-thaw cycles to disrupt cell membranes. Proteins (40 µg) were separated by SDS-10% polyacrylamide electrophoresis gel and then transferred to Immobilon-P membrane (Millipore). Analysis of G6PC expression was performed as previously described using an antibody raised against the C-terminal part of the protein [22].

HepG2 hepatoma cells were fixed with 2% paraformaldehyde in PBS and permeabilised with 0.1% saponin in PBS. The cells were incubated for one hour at room temperature with a G6PC antibody (used at 1:1000) as previously described [22]. The cells were rinsed and then incubated with goat anti-rabbit coupled to Alexa-546 (used at 1:1000, Invitrogen) for 1 h at room temperature.

2.4. Cell microscopy and FRET measurement

Cells were observed using an inverted two-photon laser scanning microscope Axiovert 200M (LSM510 NLO META, Carl Zeiss) equipped with a tunable IR femtosecond Ti:Sa laser (Tsunami, Spectra-Physics). Cells were maintained at 37°C in a humidified atmosphere containing 5% CO₂ using an on-stage incubator (PeCon, Germany). Confocal images of cyan and yellow fluorescence were detected with the emission band-pass filters 480/40 and 535/30 nm, respectively, using an excitation wavelength of 420 nm. Images were acquired using a 63×/1.4 oil immersion objective. Pearson's coefficient was calculated using the JACoP plugin for ImageJ [23].

FRET efficiency in living cells was assessed in confocal mode using the acceptor photobleaching method and using fluorescence lifetime imaging (FLIM) after two-photon excitation. Confocal detection of CFP/YFP was performed using 458/514 nm excitation wavelengths and 480-520/545-610 nm spectral filters, respectively. Repeated scans with unattenuated 514 nm illumination were used to photobleach YFP. After complete YFP bleaching, fluorescence intensities of CFP and YFP were measured

1 using the same parameters as before photobleaching. FRET efficiency was calculated
2 using the formula $E = 1 - (I_{DA}/I_D)$. I is the emission intensity of the donor (CFP) in the
3 presence (I_{DA}) or in the absence (I_D) of the acceptor (YFP). E is the percentage of the
4 increase of the donor fluorescence after bleaching the acceptor. For FLIM, the two-
5 photon laser was tuned to 840 nm with a pulse duration of 150 fs. This wavelength was
6 settled to obtain the best fluorescence excitation of CFP without a noticeable
7 contribution of cellular autofluorescence. The irradiation intensity on the sample was
8 500 μ W at 2% transmission of the acousto-optical tunable filter (AOTF). The
9 fluorescence lifetime of CFP was measured by the time-correlated single photon
10 counting technique (TCSPC) using the counter SPC 830 (Becker & Hickl GmbH,
11 Germany).

21 2.5. G6Pase activity assay

22 Cells were homogenised in 10 mM HEPES, pH 7.3 by ultrasonication coupled with
23 freeze-thaw cycles to disrupt cell membranes. Cell extracts were then suspended (1:20
24 dilution) in 10 mM HEPES and 0.25 M sucrose, pH 7.3. As previously described, we
25 used a specific assay for G6Pase determination, a method involving β -
26 glycerophosphatase activity determinations to determine the contribution of non-
27 specific phosphatase activities from G6Pase activity [3].

36 3. Results and discussion

37 3.1 Intracellular localisation of G6Pase subunits.

38 The intracellular localisation of G6PC and G6PT, obtained from biochemical
39 and histochemical studies, suggested that both proteins localised in the ER membrane
40 [6-8]. However, no recent data based on the detection of G6Pase proteins have
41 confirmed this intracellular localisation. To address this question, we chose to label the
42 cytoplasmic termini of both G6Pase subunits with fluorescent proteins. The predicted
43 model for the G6PC structure suggests that its N terminal part is located on the luminal
44 side of the ER and the C terminal faces the cytoplasm, whereas both termini of G6PT
45 are predicted to be in the cytoplasm (Figure 1 and 2).

46 The enzymatic activity of G6Pase depends on the integrity of the amino acid
47 sequences of G6PC. Therefore, we first checked that the addition of a fluorophore to the
48 endogenous G6PC protein had no effect on its activity and cellular localisation. Cells
49 transfected with G6PC-CFP (CFP fused the C-terminus of G6PC) conserved notable
50

1 G6Pase activity (Figure 1a). This activity was approximately 50% lower than that of
2 cells transfected with the wild-type protein (Figure 1a). This was in agreement with a
3 50% lower expression of G6PC-CFP compared to G6PC in HeLa cells (Figure 1b).
4 Altogether, this suggested that the fusion of CFP to the C-terminus of G6PC did not
5 substantially alter the intrinsic G6Pase activity of the protein. As previously suggested
6 for the wild-type protein [8], we showed that G6PC-CFP was located in the nuclear
7 membrane and in vesicular structures surrounding the nucleus, which are characteristics
8 of ER membranes (Figure 1c). Surprisingly, G6PC-CFP was also located in punctuate
9 vesicles within the cytoplasm and also close to the surface of the cell (Figure 1c). To
10 confirm that the cellular localisation of the G6PC-CFP construct was the same as the
11 endogenous one, we used an antibody specific for G6PC allowing its detection by
12 immunohistochemistry in G6PC-expressing cells [22]. We showed that endogenous
13 G6PC expressed by the human hepatoma cell line HepG2 exhibited the same
14 intracellular localisation as G6PC-CFP overexpressed in HeLa cells (Figure 1d).
15 Finally, we used a time lapse process, which allowed us to follow up the movement of a
16 point during a determinate time, to determine whether G6PC-CFP fluorescent points
17 were mobile vesicles. We showed that G6PC-CFP expression points moved rapidly (0.5
18 $\mu\text{m/s}$) with no orientated trajectory (Movie 1).

27
28
29
30
31

32 Concerning G6PT, the addition of the YFP fluorophore to the C-terminal part of
33 G6PT led to a punctuate pattern in the vicinity of the nucleus similar to that of G6PC-
34 CFP (Figure 2a). Some vesicles were present in the cytoplasm but were localized nearer
35 the nucleus compared to the G6PC-CFP vesicles (Figure 2a). In addition, it must be
36 noted that localisation near the plasma membrane was not observed with G6PT-YFP.
37 Experiment with insertion of the YFP to the N-terminal part of G6PT was also carried
38 out. However, the addition of the YFP fluorophore to the N-terminal part of the protein
39 led to a broader and more diffuse localisation (Figure 2b). YFP is highly hydrophilic.
40 Thus, the presence of the fluorescent protein on the N terminus of G6PT likely
41 perturbed its co-translational insertion process in the ER, thereby explaining the
42 misaddressing of the chimeric protein YFP-G6PT. In agreement with the latter
43 rationale, mutations inducing a destabilisation of G6PT proteins are mainly localised in
44 the N-terminal part and in the first loop of the protein [19]. An exogenous signal peptide
45 could have been added to the N-terminus end of the YFP-G6PT construct in order to
46 force N-terminal insertion in the membrane. However, such a chimera protein might
47 probably not behave as the endogenous G6PT, and results obtained with such a protein
48

64
65

1 would have been difficult to interpret. For further experiments, we thus used G6PT-YFP
2 chimeras. Finally, using time lapse process, we analysed the behaviour of G6PT-YFP
3 fluorescent points. On the contrary to G6PC-CFP, G6PT-YFP expression points did not
4 move throughout cytoplasm (data not shown).
5
6

7 Both proteins were overexpressed in HeLa cells to analyse their putative
8 colocalisation. The superposition of G6PC-CFP and G6PT-YFP fluorescence patterns
9 suggested that both proteins were colocalised in the perinuclear area (Figure 3c). We
10 calculated the Pearson's coefficient (PC) of correlation to quantify the degree of
11 colocalisation between G6PC-CFP and G6PT-YFP. The PC measures the intensity of
12 fluorescence of each pixel in both channels and compares the channels to determine the
13 amount of correlation. A PC of 1.0 indicates complete colocalisation; a PC of 0 means
14 no correlation and a PC of -1.0 means they are negatively correlated [23]. G6PC-CFP
15 showed a high degree of colocalisation with G6PT-YFP based on PC values of $0.86 \pm$
16 0.08 (Figure 3).
17
18
19
20
21
22
23
24

25 To resume, the G6Pase complex was not affected by the labelling of either
26 G6PC or G6PT proteins on their C-termini. Using G6PC-CFP and G6PT-YFP chimera
27 proteins, we demonstrated for the first time that both G6Pase subunits strongly
28 colocalised within the cell. In addition, the presence of G6PC, but not G6PT within
29 punctuate structures close to the plasma membrane was also detected. We then took
30 advantage of these fluorescent chimeras for investigating a direct interaction between
31 G6Pase subunits.

40 *3.2 Analysis of the interaction between G6PC and G6PT using FRET.*

41 To assess the putative FRET between G6PC-CFP and G6PT-YFP proteins, we
42 determined the energy transfer efficiency by acceptor photobleaching approaches.
43 Acceptor photobleaching approaches with CFP- and YFP-tagged proteins are simple
44 and prevent problems associated with any putative difference in expression levels: when
45 FRET occurs, the fluorescence of the CFP donor increases after bleaching the YFP
46 acceptor chromophore, and this is recognised as a relevant signature for FRET [25].
47
48
49
50
51
52

53 HeLa cells were transfected with G6PC-CFP and G6PT-YFP proteins and
54 subjected to intense illumination at 514 nm to bleach YFP (100 scans). In the bleached
55 region, we observed a complete loss of yellow fluorescence (compare figure panels 4d
56 with 4b) but no increase in cyan fluorescence (compare figure panels 4a with 4c),
57 indicating the absence of FRET from CFP to YFP before bleaching (Figure 4e). Thus,
58
59
60
61
62
63
64
65

1 these experimental conditions did not allow us to demonstrate the existence of an
2 intermolecular FRET between labelled G6PC and G6PT.

3
4 The absence of detected FRET could be due to the cell model used. HeLa cells
5 do not express endogenous G6Pase and could not offer the conditions necessary for an
6 interaction between G6PC and G6PT specific to gluconeogenic cells. To test this
7 hypothesis, we performed the same experiment in a renal cell line (NRK cells, which
8 are able to produce glucose; Soty and Mithieux, unpublished data). However, as in
9 HeLa cells, these experimental conditions did not allow us to demonstrate FRET
10 between G6PC and G6PT (data not shown).

11
12 Another explanation for the absence of detectable FRET could be that the rapid
13 movement of G6PC-CFP-labelled vesicles perturbs image acquisition and FRET
14 measurements. Indeed, we showed that G6PC-CFP expression points moved rapidly
15 (0.5 $\mu\text{m/s}$) (3.1, Movie 1). To detect FRET using acceptor photobleaching approaches,
16 CFP images must be taken before and after YFP photobleaching. Between these two
17 acquisitions, CFP labelled vesicles might disappear or change their localisation due to
18 their putative movements in the x, y or z spatial plans. To test this hypothesis, we
19 performed the detection of FRET by the single photon counting (FLIM), a method
20 insensitive to the variation of fluorescence intensity. FLIM measures the effect of the
21 acceptor on the excited state lifetime of the donor. When FRET is occurring between the
22 donor and the acceptor, the donor lifetime is reduced [26]. The mean lifetime of the
23 double exponential decay of G6PC-CFP was measured to be 1.9 ns in the perinuclear
24 endoplasmic reticulum either in the absence or in the presence of the G6PT-YFP,
25 indicating no FRET between these labels (Supplemental figure 2, white circles). One
26 should notice, however, the strong variation in the G6PC-CFP lifetime values in
27 vesicular structures close to the cell periphery, precluding quantitative FRET analysis
28 using FLIM (Supplemental figure 2).

29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63 64 65 *3.3 Analysis of the interaction between G6PT termini.*

66 The predicted model for the G6PT structure suggests that G6PT is anchored in
67 the ER membrane by 10 transmembrane helices and has both termini facing the
68 cytoplasm [19]. The interaction between these termini has not been addressed yet. To
69 study the conformational behaviour of G6PT ends, we generated a G6PT protein tagged
70 on the C and N termini with CFP and YFP, respectively (CFP-G6PT-YFP).

1 The intracellular distribution of the doubly labelled G6PT subunit (CFP-G6PT-
2 YFP protein) was similar to the simply labelled subunit G6PT-YFP (Figure 5a, b). After
3 YFP fluorescence extinction under the conditions previously described (3.2), we
4 showed an increase in cyan fluorescence, demonstrating the existence of a FRET
5 phenomenon between CFP and YFP before bleaching (compare figure panels 5a with
6 5c). The ratio of the YFP/CFP fluorescence intensities was constant and not correlated
7 with FRET efficiency. This observation illustrated that the labelling stoichiometry was
8 1:1 and that both fluorophores were never expressed independently (Figure 5e) [27].
9 The mean intramolecular FRET efficiency of the CFP-G6PT-YFP protein was 27%.
10 This result indicates that the G6PT protein adopted a wrapped conformation, so that
11 FRET occurred between its two extremities [27]. From these data, we estimated the
12 distance between the C and N termini of G6PT to 5.8 nm (supposing the Förster radius
13 for CFP/YFP pair is 4.9 nm [28]).

14 Some data [15, 29] have argued for the existence of a direct influence of G6PC
15 protein on G6PT transport function. We tested the hypothesis that the presence of
16 unlabelled G6PC could induce a conformational change to the CFP-G6PT-YFP chimera
17 detectable by a modification of its FRET efficiency. The co-expression of unlabelled
18 G6PC with CFP-G6PT-YFP in HeLa cells did not modify the FRET efficiency of the
19 doubly labelled G6PT (23.64 ± 6.29 vs. $25.61 \pm 9.86\%$). These results suggest that
20 G6PC did not modify the interaction between G6PT termini.

21 *3.4 Effect of GSD-1 mutations on G6Pase subunit intracellular localisation and on* 22 *G6PT intramolecular FRET.*

23 Mutations identified in GSD-1 patients have been studied *in vitro* to assess their
24 effect on protein stability and enzymatic activity [18, 19, 30]. From these data, we
25 selected mutations located in different parts of G6PC or G6PT which did not affect the
26 stability of the proteins but annulled or strongly decreased their enzymatic activity
27 (Table 1) [30]. Our fluorescent chimera enabled us for the first time to test whether the
28 decrease of G6Pase activity due to GSD-1 mutations was linked to a cellular
29 mislocalisation of G6Pase subunits. Concerning G6PC, we introduced some GSD-1a
30 mutations on the G6PC-CFP construct (E110K, A241T, G184R and G222R). We did
31 not observe an effect of any of these mutations on the cellular localisation of G6PC-
32 CFP. As an example, the E110K mutation, which induced a complete loss of G6Pase
33 activity (Table 1) [30], exhibited the same localisation pattern as the wild-type protein

1 (Figure 6b). Concerning G6PT, we introduced some GSD-1b mutations in the CFP-
2 G6PT-YFP construct (S54R, H301P, and A367T). We did also not observe an effect of
3 any of these mutations on the cellular localisation of G6PT-YFP. Indeed, the S54R
4 mutation, which induced a complete loss of G6Pase activity, or the H301P mutation,
5 which kept about 25% of wild type G6Pase activity (Table 1) [30], exhibited the same
6 localisation pattern as the wild type CFP-G6PT-YFP construct (Figure 6c-h).
7
8
9

10 GSD-1b disease is characterised by the loss of G6Pase activity due to G6P
11 transport deficiency [24]. In addition to defects in glucose homeostasis, GSD-1b
12 patients present symptoms of neutropenia and myeloid dysfunction [31]. These data are
13 consistent with the idea that G6PT is not just a G6Pase partner but also a key protein for
14 normal neutrophil function. Therefore, knowledge of G6PT structure-function
15 relationships could be crucial for the understanding of both G6Pase function and GSD-
16 1b pathophysiology. To identify whether the loss of function of G6PT observed in
17 GSD-1b patients is associated with a spatial rearrangement between its C and N termini,
18 we tested the influence of some GSD-1b mutations on the FRET efficiency of CFP-
19 G6PT-YFP. However, the presence of the selected mutations did not affect the FRET
20 efficiency of the CFP-G6PT-YFP construct (Figure 7). In summary, our results strongly
21 suggest that the decrease or the loss of G6Pase activity in GSD1 patients was not linked
22 to a mislocalisation of any G6Pase subunits or to an alteration of the interaction
23 between G6PT termini.

38 **4. Conclusion**

39 In conclusion, this study constitutes an original focus on the intracellular
40 distribution of G6PC and G6PT. We suggest that both proteins are strikingly co-
41 localised in the intracellular membranes close to the nucleus. Moreover, G6PC, but not
42 G6PT, is also present in vesicles throughout the cytoplasm and is subject to rapid
43 motion within the cell. For the first time, our results demonstrated that G6PT C and N-
44 termini are separated by about 5-6 nm strongly suggesting that G6PT adopts within the
45 ER membrane a wrapped conformation. Moreover, the intramolecular interactions are
46 strong enough for the G6PT conformation be maintained either in the presence of G6PC
47 or in the presence of mutations identified in GSD-1b patients.

Figure legends

Figure 1: Characteristics of the G6PC chimera.

HeLa cells were transfected with the empty pSVK3 plasmid (mock) or with plasmids coding for the human wild-type G6PC or coding for G6PC-CFP. **a.** G6Pase activities assayed in the lysates of transfected HeLa cells. Results are expressed as means \pm SEM (n=4). * P<0.05, significantly different from mock value (Student's t-test for unpaired data). **b.** Representative immunoblot for G6PC illustrating the sizes of the wild-type and chimera G6PC proteins. Molecular weight of the protein marker is indicated on the right of the figure. **c,d.** Representative confocal images of **(c)** G6PC-CFP in HeLa cells **(d)** endogenous G6PC in HepG2 cells. Bar = 10 μ m

Figure 2: Characteristics of the G6PT-CFP constructs.

Representative confocal images of **(a)** G6PT-YFP and **(b)** YFP-G6PT expressed in HeLa cells. Bar = 10 μ m

Figure 3: Colocalisation of the G6PC and G6PT chimeras.

Representative confocal images of **(a)** G6PC-CFP by CFP excitation and **(b)** G6PT-YFP by YFP excitation in HeLa cells transiently expressing a 1:1 ratio of G6PC-CFP and G6PT-YFP constructs. **(c)** Overlay of CFP and YFP emissions from the same cells. Bar = 10 μ m. Pearson's coefficients (mean of eight independent experiments) indicate the degree of colocalisation between both chimera.

Figure 4: Photobleaching of yellow fluorescence associated with G6PT-YFP in HeLa cells.

Representative images of G6PC-CFP **(a,c)** and G6PT-YFP **(b,d)** co-expressed in HeLa cells. The images were acquired immediately before **(a, b)** and after **(c, d)** bleaching (see 2.4 for details). The bleached region is delimited by a white circle. Bar = 10 μ m. **e.** Pixel intensities of CFP fluorescence acquired before and after photobleaching. Results represent the mean \pm SD of eight independent experiments.

Figure 5: Photobleaching of yellow fluorescence associated with CFP-G6PT-YFP.

Confocal imaging of cyan **(a, c)** and yellow **(b, d)** fluorescence of CFP-G6PT-YFP expressed in HeLa cells. The images were acquired immediately before **(a, b)**, and after **(c, d)** bleaching. The bleached region is delimited by a white circle. Bar = 10 μ m. **e.** FRET efficiencies (y) (see 2.4 for calculation) for doubly labelled G6PT according to the ratio of corrected fluorescence intensities for CFP and YFP (x).

Figure 6: Effect of GSD-1 mutations on G6Pase subunit localisation.

Representative confocal images of wild-type **(a)** and E110K **(b)** G6PC-CFP in HeLa cells. Representative confocal images of cyan (left panels) and yellow (right panels) fluorescence of wild-type **(c, d)**, S54R **(e, f)** or H301P **(g, h)** CFP-G6PT-YFP constructs in HeLa cells. Bar = 10 μ m.

Figure 7: Effect of GSD-1b mutations on FRET efficiency of CFP-G6PT-YFP.

FRET efficiency was calculated as previously described. Results are expressed as means \pm SEM (n =3).

Table 1: GSD-1 mutations used in the study

GSD-1 mutations located in loops of G6PC and G6PT, with no effect on protein stability or G6Pase activity were chosen. Table indicates the amino acids targeted by the mutation, its localisation on the predicted model of the protein and its effect on G6Pase activity compared to wild type [18, 19, 30].

Movie 1 (MOV file): HeLa cells were transfected with the G6PC-CFP construct. Confocal images of cyan fluorescence were detected with the emission band-pass filters 480/40 nm using an excitation wavelength of 420 nm. Images were acquired using a 63×/1.4 oil immersion objective every sec for over 70 sec.

Movie 2 (MOV file): HeLa cells were transfected with the G6PT-YFP construct. Confocal images of yellow fluorescence were detected with the emission band-pass filters 535/30 nm using an excitation wavelength of 514 nm. Images were acquired using a 63×/1.4 oil immersion objective every 0.4 sec for over 85 sec.

Supplemental material

Supplemental Figure 1: Amino acid sequences of the chimera proteins used in this study.

Underlined texts correspond to the CFP or YFP sequences. Texts highlighted in grey correspond to G6PC or G6PT sequences. Nucleic acids coding for the stop codon of G6PC (**A**), G6PT (**B**), CFP (**C**) or YFP (**D**) and nucleic acids from the cloning vector located between G6PC and CFP (**A and C**) or between G6PT and YFP (**B and D**) were removed by site-directed mutagenesis. **E**. Nucleic acids coding for the nuclear localisation signal from simian virus large T-antigen contained in the pECFP-Nuc vector were removed by the cloning strategy.

Supplemental Figure 2: Analysis of the G6PC-CFP and G6PT-YFP interaction using FRET- FLIM.

G6PC-CFP lifetimes measured by the TCSPC method in HeLa cells co-expressing G6PC-CFP and G6PT-YFP are represented before (**a**), and after (**b**) bleaching (see 2.4 for details). The bleached region is delimited by a white circle. Lifetime is indicated by the color bar.

Table 1

Amino acid changes	Location	Effect on G6Pase activity
GSD-1a mutations		
E110K	1 st Loop	Total inactivation
A241T	3 rd loop	21.3 % of wild type activity
G184R	5 th loop	Total inactivation
G222R	6 th loop	4 % of wild type activity
GSD-1b mutations		
S54R	1 st Loop	Total inactivation
H301P	3 rd loop	24.2 % of wild type activity
A367T	9 th loop	23.1 % of wild type activity
