Abstract

Background: Effort-reward imbalance (ERI) is an established conceptualisation of work stress. Although a validated effort-reward questionnaire is available for public use, many epidemiological studies adopt shortened scales and proxy measures. To examine the agreement between different abbreviated measures and the original instrument we compared different versions of the effort-reward scales available in 15 European cohort studies participating in the IPD-Work (Individual-participant-data meta-analysis in working populations) Consortium.

Methods: Five of the 15 studies provide information on the original ('complete') scales measuring 'effort' and 'reward', whereas the 10 remaining studies used 'partial' scales. To compare different versions of the ERI scales, we analyse individual-level data from 31,790 participants from the five studies with complete scales.

Results: Pearson's correlation between partial and complete scales was very high in case of 'effort' (where 2 out of 3 items were used), and very high or high in case of 'reward', if at least 4 items (out of 7) were included. Reward scales composed of 3 items revealed good to satisfactory agreement, and in one case, a reward scale consisting of 2 items only demonstrated a modest, but still acceptable degree of agreement. Sensitivity and specificity of a composite measure, the ratio of effort and reward, comparing partial versus complete scales ranged between 59-93% and 85-99%, respectively. Complete and partial scales were strongly associated with poor self-rated health.

Conclusion: Our results support the notion that short proxy measures or partial versions of the original scales can be used to assess effort-reward imbalance.

Introduction

Chronic psychosocial stress at work has been identified as a risk factor of several major non-communicable diseases, most notably cardiovascular disease and depression. Work stress was shown to influence the onset as well as disease prognosis (Schnall 2009; Stansfeld 2006; Tsutsumi 2004; Nieuwenhuijsen 2010; Steptoe and Kivimäki 2012) , with some noticeable exceptions (Belkic 2004). Importantly, work stress also contributes to poor self-rated health (Salavecz 2010), functional limitations (Kuper 2002), sick leave (Head 2007) and disability (Blekesaune 2005; Dragano 2007). To further improve understanding of stress related disease existing evidence from small and medium size studies must be approved using large scale samples which allow the calculation of precise estimators of effect, subgroup analyses and associations with outcomes of smaller incidence. One promising strategy is the pooling of data from available studies in order to improve statistical power and precision of prediction of work stress-related morbidity and mortality risks. Such an approach requires comparable measures of exposure across studies which are based on theoretical concepts of stress at work.

While several such theoretical concepts have been developed (Cartwright and Cooper 2009), the following theoretical models are often applied in prospective epidemiological studies: the demand-control (DC) (or job strain) model (Karasek and Theorell 1990), focusing on distinct job task profiles, the model of organisational justice (Greenberg 20010, Elovainio 2002), dealing with fairness of procedures and interactions, and the effort-reward imbalance model (ERI) (Siegrist 1996) which provides the basis of the current report. The ERI model addresses the work contract and the principle of social reciprocity lying at its core. Rewards received in return to efforts spent at work include money, esteem, and career opportunities (promotion, job security). The model proposes that lack of reciprocity (high effort in combination with low reward) generates negative emotions and psychobiological stress responses with adverse long-term effects on health. This model is usually measured by a psychometrically validated questionnaire available in two highly comparable versions, an original version containing 23 Likert-scaled items and a short version containing 16 items measuring the two theoretical dimensions 'effort', and 'reward', and an additional personal factor 'over-commitment', in terms of uni-dimensional scales (Siegrist 2004; Siegrist 2009; Leineweber 2010; Li 2012, Li 2012a, Magnavita et al. 2012).

While a uniform application of these measures in epidemiological investigations is desirable, financial and time constraints often result in the use of even shorter sets of questions, thus precluding an appropriate test of the model by applying abbreviated or proxy measures. Nevertheless, it is worthwhile to compare the psychometric properties of these latter measures with the original measurement. If an acceptable agreement between these different measures is observed, it would be reasonable to pool data from available studies in order to improve statistical power and precision of prediction of work stress-related morbidity and mortality risks.

In this article, we make an inventory of different operational measurements of the ERI model in 15 prospective European cohort studies. In order to assess the quality of measurements based on partial scales, we use data from 5 studies which contained the original ERI scales to test the validity of partial proxy measures by comparing these scales with the original scales.

Methods

Study context

This study is part of the IPD-Work ("Individual-participant-data meta-analysis in working populations") consortium of European cohort studies (Fransson 2012; Nyberg 2012). The aim of the consortium is to establish a large-scale knowledge base for advanced research on adverse health effects of work stress. To this means, data from available European cohort studies will be harmonized and jointly analysed. The task of comparing full version of the questionnaire to shorter versions has already been accomplished with regard to the DC model (Fransson 2012). In this article, we test the comparability of different measurements of the ERI model.

Study population and assessments

To assess the concordance between different scales measuring the ERI model we examined the agreement between the full original scales that were available from 5 studies and the partial proxy scales applied in the remaining 10 investigations (a short description of these studies is given in **Appendix 1**). The 5 studies with original scales were HNR (Heinz Nixdorf Recall Study, Germany); SOEP (German Socio-Economic Panel Study), SLOSH (Swedish Longitudinal Occupational Survey of Health, Sweden), GAZEL (GAZ and ELectricité Study, France), and WOLF-F (Work, Lipids and Fibrinogen, Norrland Follow-up study, Sweden). Response rates of those studies range from 56% (HNR) to 73% (GAZEL).

Partial proxy scales were available from BELSTRESS, Belgium, COPSOQ-2 (Copenhagen Psychosocial Questionnaire Study), DWECS (Danish Work Environment Cohort Study), IPAW (Intervention Project on Absence and Well-being Study) and PUMA (Copenhagen Burnout Inventory Study), Denmark, FPS (Finnish Public Sector study), NWCS (Netherlands Working Condition Survey) and POLS (Permanent Onderzoek Leefsituatie/ Continuous Survey on Living Conditions), Netherlands, the Whitehall II study (WHII), UK, and the WOLF-Stockholm study, Sweden.

Participants with complete data on ERI scales were included in these analyses, yielding an analytic sample of 31,790 employed men and women. The individual questionnaire items of the partial proxy scales available from the other 10 studies are presented in **Table 1**.

Statistical analyses

We applied the following procedure. First, we restricted the analysis to the two scales ‘effort’ and ‘reward’, measuring the extrinsic components of the ERI model. Here, the original short versions were used from the 5 studies with 3 items measuring ‘effort’ and 7 items measuring ‘reward’ (referred to as ‘complete scales’). In accordance with the core theoretical notion, we additionally constructed a ratio of the two scales to quantify the degree of mismatch between effort and reward at individual level, according to established procedures (Siegrist 2004; Siegrist 2009; Leineweber 2010, Li 2012). By dichotomizing the effort-reward ratio (ER-R) at the cut-point of 1.0 (where efforts and rewards are equal) an exposure measure of work stress was available for all individuals. Proxy measures of the two scales were then defined from available information of the 10 remaining studies. Given a relatively high degree of heterogeneity of the wording of items and their response format, different scales were defined by consultation of the investigators who were responsible for the studies. As a result, 2 partial ‘effort’ scales, 7 partial ‘reward’ scales and 7 partial ER-R measures were identified (**Table 1**). Items and scales are available on request. The specific partial proxy scales available in each IPD cohort study are: Belstress (Effort=A/Reward=E), DWECS and COPSOQ-2 (B/ A), FPS (B/ B), IPAW (B/ D), NWCS and POLS (B/ G), PUMA and WOLF-Stockholm (B/ C), WHII (B/ F). Finally, the partial proxy scales were replicated in the five studies available for validation, and full and partial scales were compared.

Mean scale values were computed for each participant and for all complete and partial scales. Associations between 'effort' and 'reward' scales were ascertained using Pearson's correlation

coefficients with accompanying 95% confidence intervals using Fisher's transformation.

Sensitivity, specificity and Kappa (κ) statistics were calculated to evaluate the agreement between the different ER-R measurements. The following interpretations of the Kappa statistics were given: 0.00-0.20 indicates slight agreement, 0.21-0.40 fair, 0.41-0.60 moderate, 0.61-0.80 good/substantial agreement, and 0.81-1.00 a very good/almost perfect agreement (Landis 1977).

At last, we examined associations between the alternative ERI scales and health as a relevant theoretical criterion for scale validity. A single-item measure of self-rated health (SRH) was available for all studies. Using logistic regression we analysed if high stress in terms of ER-R values >1 of the respective original or proxy scale was related to poor self-rated health (defined as very bad, bad, neither good nor bad health). Regressions were conducted separately for each of the five studies and random-effects meta-analysis summary estimates were calculated over these results.

All analyses were performed using SAS version 9.2 (SAS Institute Inc., Cary, North Carolina, USA), except meta-analyses we conducted with Stata/MP, version 11.1.

Results

Sample characteristics

Concerning the socio-demographic composition, the 5 study samples were comparable with respect to their mean age. In 3 studies approximately half of the participants were women, whereas their proportion was lower in the GAZEL and WOLF-F studies (**Table 2**).

Correlation between partial and complete scales

Pearson's correlation coefficients between the complete scales 'effort' and 'reward' and the alternative partial proxy versions of these scales are displayed in **Table 3**. In all 5 studies the two partial proxy scales measuring effort showed high correlation ($r > 0.92$), thus representing the original measurement equally well. More variation was observed across the 7 partial reward scales. Scales A and B demonstrate a high degree of accordance between all 5 studies, with all coefficients ranging between $r = 0.90$ and $r = 0.98$. Again, these partial scales containing 4 or 5 of the standard items represent the original scale to a highly satisfactory degree. To a somewhat lesser extent, this is the case for the partial scales E and F where coefficients range from $r = 0.83$ to $r = 0.93$. These scales contain only 3 out of 7 standard items of the original scale. The relationships between the complete scale and the partial proxy scales C, D and G were weaker, but still acceptable with coefficients

ranging from 0.72 to 0.87. It should be noted that the reward scale G is restricted to 2 standard items, thus representing only part of the more comprehensive original construct. The strength of these associations was reasonably similar across the 5 studies. Taken together, there is statistical evidence to support the use of the 2 partial scales of ‘effort’ and the 7 partial scales of ‘reward’ as proxies of the respective original scales.

Specificity and sensitivity

Table 4 shows the results of analysis of sensitivity and specificity for ER-R based on partial proxy scales using complete scales as the criterion. Sensitivity and specificity ranged between 59-93% and 85-99% depending on the scale and study. High agreement is observed for ER-R based on effort scale B and reward scales A and F. To a lesser extent, this is the case for ER-R from effort scale B combined with reward scales B, D or G. Agreement for effort scale B- reward scale C, and effort scale A- reward scale E are lower, but still acceptable, in particular concerning the sensitivity analyses. In all analyses specificity measures are substantially higher than sensitivity measures. Kappa statistics varied for the different scales with good agreement in four of the seven alternative ratios. For the combination of the effort B scale with the reward scales C, D and G agreement was generally good, with single Kappa values indicating only moderate agreement.

Associations with self-rated health

In accordance with the theoretical assumptions the original ‘full’ effort-reward ratio is strongly associated with poor self-rated health (**figure 1**). The results for five of the seven proxy scores are very close to the result for the original ER-R. Odds ratios for the ER-R scores calculated with the reward proxies F & G are slightly lower but still significantly elevated. Study specific analyses (not shown) revealed a high degree of agreement between the results from the single studies.

Discussion

This study is the first to assess psychometric properties of abbreviated versions of the scales ‘effort’ and ‘reward’ of the effort-reward imbalance model of work stress, drawn from several large European cohort studies. We observed very high correlations between the complete and proxy effort and reward scales if at least 2 effort and 4 or 5 reward items were included. Correlations were still high if at least 3 reward items were measured, but lower in one version (G) where only 2 reward items were available. Moreover, in a cross-sectional analysis the complete scale and all partial scales were strongly associated with poor self-rated health. Overall, the partial scales show acceptable degrees of agreement and may be used as proxy measures of the original scales in future analyses of pooled data from all 15 available studies.

We also calculated the sensitivity, specificity and Kappa coefficients of the different effort- reward ratios derived from partial scales by comparing them with the ratios of the complete scales. This is important in view of the contribution of this combined measure towards explaining health risks. The ratio quantifies the imbalance between effort and reward at individual level and, thus, is expected to contribute to the explanation of adverse health effects above and beyond the effects attributed to the individual scales (Siegrist 2004; Leineweber 2010; Li 2012; Li 2012a; Magnavita et al. 2012). Again, taking the diverse quality of the proposed partial scales into account, the findings of this analysis demonstrated acceptable degrees of concordance across the different combinations of scales (Table 4).

A major strength of the study is the inclusion of data from a large population providing information on effort-reward imbalance at work from more than 30,000 employed men and women recruited in the frame of 5 epidemiological studies from different European countries. Given the high number of observations a high degree of statistical precision is expected to result from respective comparative analyses. While the findings of this study offer a strong basis of generalisation beyond those derived from single cohort studies, one should nevertheless keep in mind that the samples were recruited from Northern, North-western or Western European countries. It is therefore not known to what extent they hold true in other parts of Europe and in other continents. A further limitation relates to potential bias produced by differences in the meaning of wording of single items in the translation of original scales. Although established quality criteria are usually applied in these translation processes potential differences in meaning may reduce a strict comparability of results, in particular

in case where scales were reduced to 2 or 3 items. A further limitation specifically concerning the shorter scales is that not all of the theoretical dimensions of the ERI model are captured by respective items (e.g. all dimensions of reward). This shortcoming could reduce the content validity of the respective scale. Moreover, the precision of comparison was reduced by differences in the wording and in the response format of some items from proxy measures.

There are only a few previous studies which compared ERI scales across different countries. Most notable among those is a study funded by the European Science Foundation which included data from France, Belgium, Sweden, Germany and the United Kingdom (Siegrist 2004). As a majority of these studies used the complete scales analytical emphasis was put on the factorial structure of the scales, testing goodness of fit by confirmatory factor analysis, as well as on content validity, estimating odds ratios of poor self-rated health according to the effort-reward ratio. Again, a high degree of comparability of results was obtained. Another study compared the original ERI scales and a proxy measure within a Swedish working population, again with reasonable comparability (Fahlen 2004). Moreover, in depth analyses based on item response theory were conducted by Tsutsumi and colleagues using cross-national data from different studies (Tsutsumi 2009). The results indicated a sufficient cross-country comparability of standard scales.

In conclusion, in view of prevailing constraints in applying extensive, time-consuming original scales measuring established work stress models in large-scale epidemiological studies, our findings support the notion that short proxy measures of the original scales measuring the effort-reward imbalance model can be used for data analysis in work stress research. Clearly, this is always a second best choice, but the trade-off between strong comparability of exposure measures on one hand and robustness and precision of prediction of health outcomes on the other hand needs to be considered.

Figure 1: Summary estimates for the associations between effort-reward imbalance and poor self-rated health for different ERI ratio scales (odds ratios & 95% confidence interval)

Table 1: Items in the complete and partial Effort/Reward Scales.

			PARTIAL SCALES†								
ERI Questionnaire		COMPLETE	EFFORT	EFFORT	REWARD	REWARD	REWARD	REWARD	REWARD	REWARD	REWARD
		SCALE*	A	B	A	B	C	D	E	F	G
Effort											
ERI 1	I have constant time pressure due to a heavy work load.	X	X	X							
ERI 2	I have many interruptions and disturbances while performing my job	X	X								
ERI 6	Over the past few years, my job has become more and more demanding	X		X							
Reward											
ERI 7	I receive the respect I deserve from my superiors	X			X		X			X	
ERI 11	My job promotion prospects are poor	X			X					X	X
ERI 12	I have experienced or I expect to experience an undesirable change in my work situation	X			X	X	X	X			
ERI 13	My employment security is poor	X			X	X	X	X	X		
ERI 15	Considering all my efforts and achievements, I receive the respect and prestige I deserve at work	X				X			X		
ERI 16	Considering all my efforts and achievements, my job promotion prospects are adequate	X							X		
ERI 17	Considering all my efforts and achievements, my salary / income is adequate	X			X	X		X		X	X

*This is the standard short form of the Effort/Reward Imbalance questionnaire. The long version additionally includes the following items: ERI 3: "I have a lot of responsibility in my job", ERI 4: "I am often pressured to work overtime", ERI 5: "My job is physically demanding"; ERI 8: "I receive the respect I deserve from my colleagues", ERI 9: "I experience adequate support in difficult situations", ERI 10: "I am treated unfairly at work", ERI 14: "My current occupational position adequately reflects my education and training".

†Partial scales from BELSTRESS, Belgium, COPSOQ-2 (Copenhagen Psychosocial Questionnaire Study), DWECS (Danish Work Environment Cohort Study), IPAQ (Intervention Project on Absence and Well-being Study) and PUMA (Copenhagen Burnout Inventory Study), Denmark, FPS (Finnish Public Sector study), NWCS (Netherlands Working Condition Survey) and POLS (Permanent OnderzoekLeefsituatie/Continuous Survey on Living Conditions), the Netherlands, the Whitehall II study (WHII), the UK, and the WOLF-Stockholm study, Sweden.

Table 2: Characteristics of study participants (N = 31,790)

Study	N*	Mean age (SD)	Female, N (%)
