Abstract

Background Amyotrophic lateral sclerosis (ALS) is a rapidly progressive disease of the nervous system involving both upper and lower motor neurons. The patterns of structural and metabolic brain alterations are still unclear. Several studies using anatomical MRI yielded a number of discrepancies in their results and a few PET studies investigated the effect of ALS on cerebral glucose metabolism. The aim of this study was threefold: to highlight the patterns of grey-matter (GM) atrophy, hypometabolism and hypermetabolism in patients with amyotrophic lateral sclerosis (ALS), then to understand the neurobehavioral significance of hypermetabolism and finally to investigate the regional differences between the morphologic and functional changes in ALS patients, using a specially designed voxel-based method.

Methods Thirty seven patients with ALS and 37 age and sex-matched healthy individuals underwent both structural MRI and ^{18}F - fluorodeoxyglucose (FDG) PET examinations. PET data were corrected for partial volume effects. Structural and metabolic abnormalities were examined in ALS patients compared with control subjects using two-sample t-tests in SPM. Then, we extracted the metabolic values of clusters presenting hypermetabolism to correlate with selected cognitive scores. Finally, GM atrophy and hypometabolism patterns were directly compared with a one paired t-test in SPM.

Results We found GM atrophy as well as hypometabolism in motor and extra motor regions and hypermetabolism in medial temporal lobe and cerebellum. We observed *negative* correlations between the metabolism of the right and left parahippocampal gyri and episodic memory, and between the metabolism of right temporal pole and affective theory of mind. GM atrophy predominated in the temporal pole, left hippocampus and right thalamus, while hypometabolism predominated in a single cluster in the left frontal superior medial cortex.

Conclusions Our findings provide direct evidence of regional variations in the hierarchy and relationships between GM atrophy and hypometabolism in ALS. Moreover, the ^{18}F FDG-PET investigation suggests that cerebral hypermetabolism is deleterious to cognitive function in ALS.

Keywords: amyotrophic lateral sclerosis, magnetic resonance imaging, positron emission tomography, voxel-based morphometry, hypermetabolism

BACKGROUND

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that primarily affects motor function, but also concerns extramotor systems. The degeneration of the motor system typically involves both upper motor neurons located in the primary motor cortex, and lower motor neurons from the brainstem nuclei and anterior horns of the spinal cord. The disease has a uniformly fatal outcome as a result of muscle weakness, with median survival of 2-4 years (1). The underlying pathophysiology is poorly understood and effective treatments are still needed for this neurodegenerative disease.

There is increasing awareness that ALS is a clinically heterogeneous disease (2). There is also a general recognition that ALS patients commonly present deficits in executive functions but also memory (3,4) and social cognition with impairment of both cognitive and affective theory of mind (5–7).

Magnetic resonance imaging (MRI) of the brain and spinal cord is routinely used in the diagnostic work-up of ALS, to rule out various pathological conditions that may masquerade as motor neuron disease, but rarely gives specific clues to the positive diagnosis. Automated techniques for analysing MRI images have been developed notably with statistical parametric mapping (SPM) software to carry out voxel-by-voxel analysis of the whole brain (voxel-based morphometry, VBM). Most of the studies, have reported extensive GM atrophy, not confined to motor areas (8).

Positron emission tomography (PET) combined with ^{18}F -fluorodeoxyglucose (FDG), a specific radiotracer for glucose metabolism, indicates glucose uptake by astrocytes and neurons (9) and reveals local brain activity. Early studies found reduced regional cerebral glucose utilization in patients with ALS, (10) mostly in the frontal cortex but also in other cortical territories such as the superior occipital cortex (11). More recently, other authors, adopting a voxel-by-voxel approach (12–16), have observed severe hypometabolism in the premotor cortex, postcentral gyrus, prefrontal cortex, lingual gyrus, fusiform gyrus and thalamus. They also observed an increased cerebral glucose metabolism or hypermetabolism in the medial temporal lobe, the cerebellum, the occipital cortex and brainstem. This hypermetabolism has been proposed as a possible biomarker for ALS by Pagani and colleagues (13). It is not yet known, however, whether it reflects a compensatory mechanism in the brain or deleterious metabolic activity. Nevertheless, it

is important to note that the limited PET camera resolution can give rise to partial volume effects (PVEs) that result in blurring and, therefore, an underestimation of regional activity, particularly in small structures or those with volume loss. Since previous FDG-PET studies did not correct for PVEs, the metabolic abnormalities observed in patients with ALS have to be interpreted cautiously.

The above-mentioned studies investigated different groups of nondemented patients with ALS using either brain MRI or FDG-PET (without correction for PVEs). Only one combined these two techniques in a single group of 18 patients with ALS who met the Neary criteria for frontotemporal dementia (FTD) (17). The authors assessed brain GM structural changes using VBM, and metabolic changes using FDG-PET. They concluded that the metabolic changes corresponded to the structural changes, with a few exceptions.

To our knowledge, no combined assessment of GM volume and regional cerebral metabolism has yet been carried out in nondemented patients with ALS. The goals of the present study were threefold: 1) determine both GM volume and glucose metabolism changes in a sample of patients with ALS by adopting a voxel-based approach; 2) further study the clinical significance of hypermetabolism, by assessing its relationship with selected cognitive scores; and 3) carry out a direct voxelwise comparison of the degrees of local GM atrophy and hypometabolism throughout the brain, by using a specific processing technique developed in our laboratory that has already been applied in early Alzheimer's disease (18), alcoholism (19), and the behavioural variant of FTD (20).

METHODS

Participants

Participants with ALS.

Participants were 37 patients with ALS (21 men and 16 women; mean age = 61.18 years, standard deviation = 11.11; mean level of education = 10.03 years, standard deviation = 2.96) with either bulbar ($n = 10$) or spinal ($n = 27$) onset. Patients with ALS were recruited between November 2009 and June 2014 via the ALS clinic of the neurology department of Caen University Hospital (France). All participants were native French

speakers and had a minimum level of education equivalent to a now obsolete school-leaving certificate that was generally taken at 14 years.. All the patients met the modified El Escorial criteria for probable or definite ALS (21). Exclusion criteria were the additional presence of severe and chronic illness, alcohol or drug abuse, traumatic brain injury, or an extremely severe communication problem that could seriously compromise the administration of cognitive tests. None of the patients fulfilled the criteria for a diagnosis of FTD according to the core and supportive diagnostic features of FTD detailed in Lund and Manchester's consensus statement (22). None of the patients with ALS met the criteria for a possible and/or probable behavioural variant of FTD (23). Behavioural disorders were explored in 32 patients via the short form of the Neuropsychiatric Inventory (24). None had behavioural disorders of the frontal type sufficiently severe to meet the criteria for ALS with behavioural impairment. All the patients underwent a neurological assessment that included the ALS Functional Rating Scale Revised (ALS-FRS-R) (25), Norris scale (26), and Medical Research Council (MRC, 1976) Muscle Strength Scale. They were able to speak or to write intelligibly. All the patients gave their written informed consent, and the independent regional ethics committee approved the study. Some of these patients had already been included in a previous study (5). The ALS patients underwent a neuropsychological assessment covering a range of cognitive functions (for details, see (5)).

Control groups.

Neuroimaging

To compare the neuroimaging data, we included a group of 37 healthy controls (21 men and 16 women; mean age = 61.11 years, standard deviation = 11.11; mean level of education = 11.45 years, standard deviation = 2.97). Healthy controls were recruited from the community and performed in the normal range on a neuropsychological examination assessing multiple domains of cognition including episodic and semantic memory, executive and visuo-spatial functions, language and praxis. Within a few days from recruitment, they also underwent a structural MRI and a PET using [18F] fluoro-2-deoxy-D-glucose (18FDG). These controls were closely matched for sex, age, and level of education with the group of patients with ALS.

Cognition

As most of our neuropsychological tests were original, with no available normative values, to compare the cognitive scores, we included another group of 37 healthy subjects (21 men and 16 women; mean age = 61.81 years, standard deviation = 8.84; mean level of education = 11.19 years, standard deviation = 2.60). The Mattis cut-off score was set at 130, to avoid the possible inclusion of controls with mild cognitive impairment (for details, see Table 1).

Neuropsychological assessment

Patients and controls underwent a neuropsychological assessment that evaluated a set of cognitive functions that were already described and published in a previous study (for details see (27)). In order to understand the neurobehavioral significance of cerebral hypermetabolism, we only worked on cognitive scores that could be related to brain regions showing hypermetabolism (see *infra*). This is why we chose to explore the affective theory of mind abilities and the episodic memory of ALS patients. Affective theory of mind was assessed with the Reading the Mind in the Eyes test derived from the procedure used by Baron-Cohen et al. (2001) (28). The participants had to make inferences about the affective and motivational states of others on the basis of a picture of their eyes (for more details see (29)). We then explored episodic memory, with a task in which participants had to intentionally encode a list of eighteen unrelated words. Every three words, they were subjected to an immediate free recall task. Following the study phase, there was a 20-second interval during which participants were engaged in an unrelated distractor task. Participants then had to recall as many words as possible, with no time-limit. After a 20-min interval, they were finally subjected to a delayed free recall task, again with no time-limit.

Neuroimaging data acquisition

All participants were scanned using the same MRI and PET cameras at the Cyceron centre (Caen, France): a Philips Achieva 3.0 T scanner and a discovery RX VCT 64 PET-CT device (General Electric Healthcare, respectively).

MRI data.

For each participant, a high-resolution T1-weighted anatomical image was acquired on a Philips Achieva 3T scanner using a three-dimensional fast field echo sequence (sagittal; repetition time = 20 ms, echo time = 4.6 ms, flip angle = 10°, 180 slices, slice thickness = 1 mm, field of view = 256 x 256 mm², matrix = 256 x 256).

PET data.

Each participant underwent a PET examination the day after MRI examination. FDG scans were acquired on a Discovery RX VCT 64 PET-CT device (GE Healthcare) with a resolution of 3.76 x 3.76 x 4.9 mm³ FWHM (axial field of view = 157 mm). Forty-seven planes were obtained with septa out (3D acquisition); with a voxel size of 2.7 x 2.7 x 3.27 mm³. A CT transmission scan was performed for attenuation correction before the PET acquisition. Participants were fasted for at least 6 hours before scanning. After a 30-minute resting period in a quiet and dark environment, ~180 MBq of FDG were intravenously injected as a bolus. A 10-minute PET acquisition scan began 50 minutes after injection. During data acquisition, head motion was continuously monitored with laser beams projected onto ink marks drawn on the forehead, which also served to make any necessary corrections.

Neuroimaging data handling and transformation

Preprocessing

Using the VBM5.1 toolbox (<http://dbm.neuro.uni-jena.de/vbm/vbm5-for-spm5/>), implemented in SPM5 software (Wellcome Trust Centre for Neuroimaging, London, UK), the raw MRI data were spatially normalized to Montreal Neurological Institute (MNI) space (voxel size = 1 mm³, matrix = 156 x 189 x 157) and segmented into GM, white matter (WM) and cerebrospinal fluid (CSF). The normalized GM images were modulated by the Jacobian determinants to correct for nonlinear warping only, to obtain maps of local GM volumes corrected for brain size.

FDG-PET data were first corrected for CSF and WM PVEs, using the voxel-by-voxel modified Müller-Gartner method,^(30,31) described in detail elsewhere⁽³²⁾ and already used in our laboratory.^(18–20) Using SPM5, the PVE-corrected PET data were then coregistered (rigid-body coregistration) to their respective native MRIs and normalised to MNI space by reapplying the normalization parameters estimated

from the VBM protocol described above. The resulting images underwent quantitative scaling using mean GM as a reference.

Smoothing

For the between-group comparison, and in order to blur individual variations in gyral anatomy and increase the signal-to-noise ratio, the registered MRI data were smoothed using an 8 x 8 x 8 (x, y, z) mm Gaussian kernel. PET datasets were also smoothed, using a 12 x 12 x 12 mm Gaussian kernel.

Differential Smoothing

For the direct comparison between GM atrophy and glucose hypometabolism, since the MRI and PET data had different spatial resolutions, differential smoothing was applied to equalize the effective smoothness (33, 47, 48). A Gaussian kernel of 8 x 8 x 8 (x,y,z) mm was used for the MRI data, and 7.1 x 7.1 x 6.4 for the PET data. Finally, images were masked to exclude non-GM voxels from the analysis.

W-score maps

To obtain measurements of atrophy and hypometabolism expressed in the same units so that we could undertake direct comparisons of the different modalities, we computed *W*-score maps for each patient and each imaging modality, using the healthy control group as a reference. *W* scores are analogous to *z* scores, but are adjusted for specific covariates (36)-age in the present case. The smoothed MRI and PET data were used to create *W*-score maps [(raw value for each patient) - (value expected in the control group for the patient's age) / (*SD* for each patient and each modality)]; see (18) for more details].

As the two datasets had different original spatial resolutions, the MRI data were coregistered and resliced into PET space to obtain images with the same dimensions.

Anatomical localization

GM anatomical localization was carried out using AAL automated labelling software implemented in SPM5.(37) For further information about thalamic subdivision, we used the Talairach atlas.(38) We focused on five major regions of the thalamus: medial dorsal nucleus, anterior and lateral ventral nuclei, posterior ventral nuclei, lateral posterior-pulvinar complex, and lateral dorsal and anterior nuclei.

Statistical Analyses

Between-group comparison of GM volume and metabolism

To determine the pattern of GM atrophy in the ALS group as well as glucose hypometabolism and hypermetabolism, compared to the control group, we used a two-sample t test in SPM5. This yielded three maps of statistically significant GM atrophy and metabolic abnormalities in patients relative to controls. To address the issue of multiple comparisons, for each analysis, the significant cluster size was determined using a Monte Carlo simulation program (AlphaSim) as previously done in our laboratory (39,40), with a cumulative proportion criterion of less than .05 (41). For the GM volume analysis, this equated to a cluster volume of 475 voxels and for the metabolism analyses a $k= 113$ voxels.

Correlations between hypermetabolism and selected cognitive scores

Statistical analyses were performed using Statistica 10.0 (StatSoft, Tulsa, OK, USA). The threshold of significance was set at $p = .05$ (one-tailed). We assessed correlations between the metabolism of significant clusters identified in the previous analysis showing hypermetabolism and selected cognitive tests. To this end, we extracted the mean metabolic values of the regions presenting hypermetabolism using the “Binary ROIs analysis” in SPM5 and then entered them into Statistica to assess correlations with selected scores of the patients with ALS.

Within-group comparison between morphological and metabolic alterations

Individual GM MRI W scores maps and PET W scores maps were entered in a one-paired t test analysis with one group (patients with AL) and two images per participant (i.e., MRI and PET W score maps), using SPM5. We put years of education and Mattis (total score) as confounding covariates in this analysis. Both contrasts were assessed (W -PET $>$ W -MRI and W -MRI $>$ W -PET) to generate statistical maps reflecting predominant structural abnormalities or glucose hypometabolism. To address the issue of multiple comparisons, significant cluster size was determined using a Monte Carlo simulation program (AlphaSim), with a cumulative proportion criterion of less than .05 (41). This equated to a cluster volume of 31 voxels.

RESULTS

Behavioral results

Regarding executive functions, compared with the control group, the patients exhibited significant impairment of executive functions on the Trail-Making Test B-A ($p < 0.001$), letter verbal fluency score ($p < 0.001$), and letter verbal fluency index ($p = 0.017$). The same was true for both episodic memory, measured with a classic word learning test ($p < 0.001$), and cognitive theory of mind, assessed with a false-belief task ($p = 0.009$), with a trend for affective theory of mind, assessed with the Face/Eyes test ($p = 0.062$) for details see Table 1). When comparing ALS patients with bulbar onset to those with spinal onset, we did not find any difference in their cognitive status (data not shown).

Patterns of grey matter atrophy and hypometabolism in ALS (see Fig. 1)

The comparison of GM volume between patients and controls revealed significant GM atrophy in the left postcentral gyrus, the left inferior temporal gyrus, the left paracentral lobule and the left supramarginal gyrus. We also found GM atrophy within the right precentral gyrus and the right putamen.

Hypometabolism mainly concerned the right paracentral lobule, the left inferior parietal gyrus, the thalamus bilaterally as well as the left superior medial frontal gyrus.

Patients also showed hypermetabolism mainly in the cerebellar vermis (IV, V and VII), cerebellar lobules IV and V, bilaterally within the medial temporal cortex (both hippocampus and parahippocampal gyri) and, to a lesser extent, the fusiform gyrus. All the results are listed in Table 2.

In our quest to better understand this metabolic dysfunction and investigate its neurobehavioural significance, we assessed the relationships between hypermetabolism and selected cognitive functions. Given that the medial temporal lobe is involved in episodic memory, the cerebellum is part of a motor network, and fusiform gyrus is involved in social cognition(42,43), we looked for positive or negative correlations between the metabolism of each of these regions and the relevant (and available) cognitive performances. All the significant correlations we found were negative. Thus, we observed significant negative correlations between episodic memory (immediate recall) and the metabolic value of the right

hippocampus ($r = -0.36$; $p = 0.04$), the left hippocampus ($r = -0.36$; $p = 0.04$) and the left parahippocampal gyrus ($r = -0.46$; $p = 0.007$). Concerning the delayed recall, we found significant negative correlations with the metabolic values of the left parahippocampal gyrus ($r = -0.45$; $p = 0.01$). We also found negative correlations between metabolic activity within the left fusiform gyrus and TOM-15 (cognitive theory of mind) ($r = -0.33$; $p = 0.04$) (Table 3).

Direct comparison between GM atrophy and hypometabolism in ALS patients

GM atrophy was greater than hypometabolism in the temporal lobes (left and right middle temporal poles, left hippocampus and left parahippocampus as well as left inferior temporal gyrus). This was also true in the left calcarine (Table 2).

The reverse contrast (hypometabolism > GM atrophy) only concerned the left superior medial frontal cortex.

DISCUSSION

To our knowledge, this was the first neuroimaging study to closely examine the relationship between cerebral GM volume and glucose metabolism via a direct comparison of both parameters, as well as the relationship between hypermetabolism and cognitive performance in patients with ALS. We first compared GM volume and cerebral glucose metabolism in patients versus controls, via a two-sample t test. We found 1) marked GM atrophy in the right premotor cortex, but also in extramotor regions, 2) glucose hypometabolism mainly in both thalamus and the parietal lobe, and 3) glucose hypermetabolism located bilaterally in the cerebellar vermis, medial temporal lobe, and fusiform gyrus. We then extracted the metabolic values of the main hypermetabolic clusters and correlated them with cognitive scores that were expected to depend on these brain regions. We found only negative correlations, first, between the hippocampus and left parahippocampus and episodic memory, and second between the left fusiform gyrus and cognitive theory of mind. We also conducted a voxelwise comparison of the degrees of local atrophy and hypometabolism, using a method specially designed for this purpose, and we observed that GM atrophy predominated in the bilateral middle temporal pole and the left hippocampus, while hypometabolism predominated in a single cluster located in the left superior medial frontal cortex.

Between-group comparisons

The profile of GM atrophy in our patients was in agreement with previous studies that had reported motor and extramotor GM atrophy in a parieto-temporal network (44–51), as well as the putamen (46,52–54).

The pathological involvement of the putamen in ALS may seem surprising, as patients do not typically exhibit extrapyramidal signs. However, ubiquitin immunoreactive intracytoplasmic inclusions and neuronal loss have been found in the striatonigral system in half of patients with classic motor neuron disease (55). Interestingly, in the study of Kim et al., the putamen was among the most atrophied brain regions in cognitively impaired ALS patients (54). Furthermore, the putamen has a major role in verbal fluency, working memory and speech production (56), cognitive domains frequently impaired in ALS (57). Finally, putaminal regions receive afferences from the motor, premotor cortices (53) all of which being heavily affected in this study.

Concerning the hypometabolism, our results are in line with most previous studies (12–14,16). Concerning the hypometabolism in the paracentral lobule, this result has rarely been found with ^{18}F FDG-PET. Indeed, Kew et al., using C^{15}O_2 in 12 patients with ALS, observed a significant reduction of cerebral blood flow at rest within this structure (58). Concerning the decreased uptake of ^{18}F FDG within the left inferior parietal gyrus found in our sample of patients, PET studies using [^{11}C]-flumazenil, or C^{15}O_2 , (58–60), also found reduced regional cerebral blood flow within the parietal lobe. We also found significantly lower frontal metabolism (superior medial) in our patient group that is line with the fact that they present frontal dysfunction. A study went further, showing that prefrontal hypometabolism was associated with reduced clinical functioning in ALS patients (14). Decreased glucose uptake in the thalamus has also been reported by Pagani et al., and is thought to be a metabolic signature of *C9orf72*-related ALS (61). Up to 10% of patients with ALS have a mutated gene, the most common of which is *C9orf72*. In patients with this mutation, the thalamic hypometabolism is slightly more marked than it is in sporadic ALS cases (14).

Our results confirm the brain hypermetabolism in ALS already demonstrated in previous studies (12–14,16). Concerning the brain regions that were found to exhibit increased glucose metabolism, results were

mainly in agreement with previous studies that also observed increased glucose metabolism in the medial temporal lobe and cerebellum (13,14).

Negative correlations with episodic memory and affective theory of mind

We observed significant negative correlations between episodic memory (immediate recall) and the metabolic value of the right hippocampus, the left hippocampus and the left parahippocampal gyrus. We also found negative correlations between metabolic activity within the left fusiform gyrus and cognitive theory of mind. The negative correlation between metabolism and cognitive scores means that hypermetabolism is associated with a functional deficiency of the involved brain area. Indeed, given that our patients with ALS scored more poorly than controls for episodic memory as well as for cognitive theory of mind, this result indicates that the abnormal pattern of glucose metabolism within these regions was not associated with preserved performances. This result was not expected because generally, when studies found hypermetabolism or hyperactivation, it is usually considered as the reflect of compensatory mechanisms (62,63). However, within the framework of Huntington's disease, a previous work has shown a link between hyperactivation of the precuneus and impaired performances of motor sequence learning (64). In ALS, it has been suggested that cerebral hypermetabolism reflects neuroinflammation, characterized by activated astrocytes and microglia (16), rather than compensatory neuronal activity. Neuroinflammation has a deleterious effect, and is therefore more consistent with the negative correlations we found in our patients between metabolic data and relevant cognitive scores.

This finding further highlights the potential role of cerebral hypermetabolism as a functional imaging marker for ALS.

Voxelwise comparisons between alterations

This analysis revealed differences in the relative degrees of GM atrophy and cerebral glucose hypometabolism.

Greater atrophy than hypometabolism

Atrophy was greater than hypometabolism in three main regions: the temporal lobe (anterior, lateral and medial), and the calcarine sulcus. Based on previous studies carried out in Alzheimer's disease,

frontotemporal dementia or chronic alcoholism (18,20,65,66), it is generally thought that loss of brain cells other than neurons might result in atrophy without associated hypometabolism. In ALS, an increasing number of studies have suggested that astrocytosis and/or microglia activation could be involved in the pathophysiology of the disease (67,68)

The finding of a normal, i.e. higher than expected, level of glucose metabolism in atrophic cerebral zones may also suggest that compensatory mechanisms are at work in these structures, helping to maintain a moderately high metabolic level relative to structural alterations—a hypothesis previously developed for Alzheimer's disease (69). In this disease, according to the authors, the presence of abnormally phosphorylated tau proteins that aggregate to form neurofibrillary tangles, may be one of the processes underlying severe atrophy and moderate hypometabolism in the hippocampus (69). In ALS, TDP-43 inclusions are located in neurons and astrocytes of ALS patients, not only in the motor regions, but also in the temporal lobe (70). Following the same reasoning, the presence of TDP-43 could lead to a massive neuronal loss whereas moderate hypometabolism could be explained by a compensation of the remaining neurons.

Greater hypometabolism than GM atrophy

We found that hypometabolism was more severe than atrophy in the left superior medial frontal cortex. This result suggests that ALS is characterized by genuine functional alterations (metabolic, chemical or molecular) on top of the neuronal loss, heightening the functional consequences of local GM atrophy. Supporting the notion of metabolic alterations in ALS, a study used the benzodiazepine GABA_A marker ¹¹C-flumazenil to study brain dysfunction in 17 patients (60). Flumazenil is an antagonist at the benzodiazepine subunit of the GABA_A receptor. These authors found reduced binding of ¹¹C-flumazenil in the dorsomedial prefrontal cortex notably. This may reflect the downregulation of postsynaptic GABA_A receptor expression (60). Given that glucose metabolism reflects synaptic activity (71), the detrimental effects of ALS on neurotransmission systems could explain why metabolic dysfunction precedes GM atrophy (e.g., within the frontal lobe). Greater hypometabolism than GM atrophy has also been observed in the behavioural variant of FTD (20), suggesting that this could be a remote effect of GM atrophy on metabolism, or a diaschisis. *Diaschisis* refers to a change in the metabolic activity of neurons that are anatomically or functionally

connected to a damaged area. The medial prefrontal cortex is connected to limbic structures such as the medial temporal lobe and putamen (72). The neuronal loss reflected by GM atrophy within the temporal lobe and putamen (see above) may remotely affect the metabolism of the medial prefrontal cortex, though possibly only for a limited period of time, as disconnected neurons eventually die, giving rise to different patterns of brain volume and metabolic impairment.

The study has some limitations. The major one is the existence of two groups of healthy subjects. Indeed, as our protocol did not include the neuroimaging examinations for healthy subjects, we used the scans of healthy subjects of another protocol of our laboratory. Then, the threshold that we used in this article is relatively liberal even if it has been employed in several MRI (47,51,73–78) or PET studies (14,16) in ALS. However, with a more stringent threshold we could have missed some interesting findings. Finally, this study should be replicated in a bigger group of ALS patients.

CONCLUSIONS

Taken together, our results confirm the existence of structural and metabolic changes in the brains of patients with ALS without dementia. We found that regional cerebral hypermetabolism is associated to impaired cognitive performance, which suggests that it reflects a local deleterious neuronal and/or astrocytic process. Our findings also emphasize the complex relationships between GM atrophy and hypometabolism, and the regional heterogeneity in their hierarchy. Greater GM atrophy than hypometabolism might mean either that brain tissue loss does not involve metabolically active cells, or that the metabolism of the remaining cells is higher than expected. Greater hypometabolism than GM atrophy could reflect either a disconnection mechanism, or an early stage of metabolic neuronal failure preceding cell death. Longitudinal studies are warranted to take account of the potential lapse between the different pathological processes.

The authors declare that they have no competing interests

Funding

This work was supported by the French Ministry of Health (PHRC, 2008, n° ID-RCB A01150-55) and Fondation pour la Recherche Médicale (FRM)

Authors' contributions

MSB was actively involved in this study from design to drafting. She conducted all the statistical analyses and played a central role in interpreting the results and writing the article. . FD greatly contributed to the neuroimaging part of this study. AM and AP participated in the acquisition of the cognitive data, especially in the careful screening of our cohort. FD, LC, and FE provided their critical revision of the manuscript. FV and BD supervised and coordinated the teamwork from start to finish. Their knowledge and expertise in neuropsychology, and ALS pathology were crucial for the design, analysis, and interpretation of the results of this project. They were also particularly involved in the revising of the manuscript. All authors read and approved the final manuscript.

Ethical approval

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.
