Abbreviated Title: COX-2 inhibitors and analgesia

Summary statement: The administration of a clinically active dose of the COX-2 inhibitor parecoxib reduces significantly the nociceptive flexion RIII reflex in healthy volunteers.

ABSTRACT

Background: Prostaglandins play a major role in inflammation and pain. They are synthesised by the two cyclooxygenase (COX) isoforms: COX-1, which is expressed constitutively in many cell types and COX-2, which is induced at the site of inflammation. However, unlike peripheral tissues, COX-2 is expressed constitutively in the central nervous system and may play a role in nociceptive processes. The present study aimed to investigate the role of constitutive COX-2 in the spinal transmission of nociceptive signals in humans.

Methods: We used 12 healthy volunteers to compare the effects of the specific COX-2 inhibitor sodium parecoxib (1 mg/kg) or placebo, administered intravenously in a double-blind and cross-over fashion, on the electrophysiological recordings of the nociceptive flexion (RIII) reflex. The RIII reflex is an objective psychophysiological index of the spinal transmission of nociceptive signals and was recorded from the biceps femoris after electrical stimulation of the sural nerve. Two experiments, seven days apart, were carried out on each volunteer. On each experimental day, the effects of parecoxib or placebo were tested on: 1) the RIII reflex threshold, 2) the stimulus-response curves of the reflex up to the tolerance threshold (frequency of stimulation: 0.1 Hz); 3) the progressive increase of the reflex and pain sensations (i.e. "wind-up" phenomenon) induced by a series of 15 stimulations at a frequency of 1 Hz (intensity 20% above RIII threshold).

Results: Parecoxib, but not placebo, significantly reduced the slope of the stimulus-response curve, suggesting a reduction in the gain of the spinal transmission of nociceptive signals. By contrast, the "wind-up" phenomenon was not significantly altered after administration of parecoxib or placebo.

Conclusions: Our study shows that constitutive COX-2 modulates spinal nociceptive processes and that the anti-inflammatory and antinociceptive actions of COX-2 inhibitors are not necessarily related.
Introduction

The analgesic and anti-inflammatory actions of nonsteroidal anti-inflammatory drugs (NSAIDs) have traditionally been attributed to their inhibition of peripheral prostaglandins (PG)\textsuperscript{1,2}. PGs are synthesised from arachidonic acids by two cyclooxygenase isoforms (COX1 and COX2) and play a major role in sensitising nociceptors at the site of tissue injury\textsuperscript{3}. COX-1 is constitutively expressed in many cell types whereas COX-2 is induced at the site of inflammation\textsuperscript{4}. Most conventional NSAIDs non-preferentially inhibit both COX isozymes. Their analgesic effects are thought to be mostly due to their inhibiting the COX-2 isoform, and their adverse effects from inhibiting COX-1. Thus, the development of selective COX-2 inhibitors has contributed significantly to therapeutic progress as these molecules have similar anti-inflammatory and analgesic properties but are better tolerated clinically\textsuperscript{5,6}. However, recent data on acute cardiovascular toxicity has lead to new recommendations for their use\textsuperscript{7-9}. Thus, there is active research into the mechanisms of NSAIDs action with the aim of improving their clinical use.

A growing body of experimental evidence suggests that, in addition to their well established peripheral effects, NSAIDs may also exert their analgesic action directly within the central nervous system (CNS)\textsuperscript{2,10}. Both COX isoforms are constitutively expressed in rat brain and spinal cord\textsuperscript{11,12}. COX-2 is the predominant isoform in the spinal dorsal horn and could play a role, not only in pathological inflammatory pain, but also in normal physiological pain (i.e. without inflammation). There are few experimental data confirming the role of constitutive COX-2 in normal pain processing in animal models\textsuperscript{2,13} but no information in humans. More generally, there is no direct evidence for central antinociceptive effects of selective COX-2 inhibitors in humans. However, studies
based on experimental models of inflammatory secondary hyperalgesia indirectly suggested a central action of parecoxib\textsuperscript{14} and rofecoxib\textsuperscript{15}, but not valdecoxib\textsuperscript{16}. 

In the present study we analysed the role of constitutive COX-2 in central nociceptive processes. We compared the effects on the nociceptive flexion RIII reflex of intravenous administration of parecoxib or placebo in healthy volunteers, administered according to a double-blind, cross-over design.

Parecoxib is the sulfonamide-based pro-drug of valdecoxib. It is a highly specific COX-2 inhibitor and is the only available parenterally-administered coxib\textsuperscript{17}. The RIII reflex is elicited by electrical stimulation of a cutaneous sensory nerve and is recorded from a flexor muscle on the ipsilateral limb. This polysynaptic spinal reflex is considered to be a reliable index of spinal nociceptive signal transmission as its threshold and amplitude are closely related to those of painful cutaneous sensations evoked by electrical stimulation\textsuperscript{18}. RIII reflex recordings have been used in numerous pharmacological studies related to analgesia in humans \textsuperscript{19-20}. In particular, it was used to reveal the central action of conventional NSAIDs (i.e. mixed COX1-COX2 inhibitors) on nociceptive processes\textsuperscript{21-23}. In the present study, we tested the effects of parecoxib on the RIII reflex stimulus-response curves. We also analysed the effects of parecoxib on the progressive increase of the reflex response and resulting sensation induced by repeated series of stimuli at relatively a high frequency (i.e. 1 Hz) of fixed intensity. This “wind-up” phenomenon, is due to the summation of nociceptive input over time (i.e. temporal summation) in the spinal cord and is considered to be an experimental elementary form of central sensitisation\textsuperscript{24}.

Thus, the goal of this electrophysiological study was to demonstrate in humans that COX-2 inhibitors have central effects and act on nociceptive processes independently of inflammation.
Methods

The experiments were approved by a local Ethics Committee and carried out on 12 paid healthy volunteers. The volunteers were carefully briefed about the experimental procedures and gave informed written consent for their participation in the study.

Electrophysiological recording of the RIII reflex

During the recordings, the subjects sat comfortably reclined to ensure a state complete muscular relaxation. (Fig 1) The nociceptive flexion reflex (RIII) was evoked and recorded with a computerised system (Notocord Systems, Croissy, France), using previously described techniques. Briefly, the sural nerve was electrically stimulated at a rate of 0.1 Hz using a pair of surface electrodes placed 2 cm apart on the degreased skin overlying the nerve within its retromalleolar path. The electrical stimulii consisted of trains of six rectangular 1 ms pulses delivered over 12 ms from a constant current stimulator. Electromyographic responses were recorded from the ipsilateral biceps femoris muscle using a pair of surface electrodes placed 2 cm apart on the degreased skin over the muscle. The electromyographic responses were then amplified, digitised and full-wave rectified, and the RIII response from the resulting integrals. The reflex responses were identified as multiphasic signals and integrated in a time window from 90 to 180 ms after stimulus onset. This time-window restriction avoids any tactile (RII) reflex that can occur between 50 and 70 ms after stimulation or any artifacts produced by involuntary movements that can be observed as early as 250 to 300 ms after stimulation. Each individual experiment started with a control period during which the stimulus was applied at an intensity 20% higher than the threshold required for stable RIII reflex responses. This control period was considered a prerequisite before starting the pharmacological procedure. The stimuli elicited slightly painful sensations similar to pinprick and were described by the subjects as originating from the stimulating
electrodes and projecting into the distal cutaneous receptive field of the sural nerve on
the lateral side of the foot.

**Experimental procedure**

This pharmacological study was organised as a double-blind, cross-over trial. We
randomly assigned a placebo (saline) or 1 mg/kg of parecoxib (Laboratoire Pfizer, Paris,
France) in a 10 ml volume of 10 ml, which was injected intravenously over a period of 10
min, with a maximum parecoxib dose of 80 mg. This dose was chosen because it was in
the range used in clinical trials\textsuperscript{27-28}. The maximum dose corresponds to the daily
maximum dose authorised for clinical use in France. The experiments were carried out
in the volunteers twice, with each experiment separated by an interval of seven days.
Six stimulation sequences were used on each experimental day: two before injection
(i.e. control period), and then at 20, 40, 60 and 80 min after administration of parecoxib
or placebo. Each sequence consisted of: (1) determining the RIII reflex threshold
(defined as the average minimal current that elicited the reflex response) by four
successive sequences of increasing and decreasing the stimulus intensity by steps of
0.5 mA; (2) building of the recruitment curve for the reflex as a function of stimulus
intensity by increasing progressively the stimulus intensity by steps of 1 mA to the
tolerance threshold at a frequency of 0.1 Hz (i.e. 6 stimuli/min); (3) applying a series of
15 stimuli at 1.2 times the threshold at a frequency of 1 Hz to analyse the "wind-up"
phenomenon. After each "wind-up" sequence, the subjects were asked to use a 100 mm
VAS, graduated from 0 (no pain) to 100 (worst possible pain), to rate both the sensation
evered by the first stimulus in each series and the maximum pain produced by any of
the stimuli. Blood pressure, heart rate and SaO2 were monitored during the
experimental sessions. Side effects such as nausea, vomiting, sedation, dysphoria and
hallucinations were recorded when present. Sedation was scored using the following

**Data analysis**

Data are expressed as means ± SEM. The reflex threshold was defined as the minimum intensity inducing an RIII response for at least 50% of the stimuli. The tolerance threshold was the maximum tolerable stimulation intensity defined by the volunteer during recording of the recruitment curve. Each reflex response was expressed as a percentage of the maximum response observed during recording of the control recruitment curve (i.e. before the injection) to allow analysis of the group data. Recruitment curves were normalised between 0 and 20 mA according to the last observation carried forward method, such that when the tolerance threshold was <20 mA, the final value obtained for the reflex was assigned to all the higher intensities in the series. The wind-up phenomenon was analysed by expressing each response during the sequence of 15 stimuli at 1 Hz as a percentage of the first response. We used Wilcoxon’s signed ranks test to compare paired data. The areas under the mean recruitment curves (AUC) and the mean "wind-up" curves were calculated and used to compare the effects of the placebo and the parecoxib. A repeated-measures analysis of variance was used to test treatment, subject, sequence and period effects. Results were considered significant at P < 0.05.
Results

Twelve volunteers (6 men, 6 women, aged 21-40 years), completed the two sessions of the study. The mean dose of parecoxib administered intravenously was: 57.0 ± 12.0 mg. No side effects were reported with either the placebo or parecoxib.

Effects of Parecoxib on the Recruitment Curve of the Nociceptive Flexion Reflex

The area under the RIII reflex recruitment curves (AUC) were similar before the injection of parecoxib or placebo (Fig 2). After administration of parecoxib, the AUC progressively and significantly decreased between 20 to 60 minutes, returning to baseline values at 80 minutes (Fig 2A). By contrast, we observed no significant change of AUC after administration of the placebo. The effects due to parecoxib were significantly different from those due to placebo (p< 0.05) at 40 and 60 minutes. The effects on the recruitment curve were not influenced by the sequence (parecoxib-placebo or placebo-parecoxib) or the period (first or second session).

As illustrated in Fig 3, the decrease in AUC was due to the slope of the recruitment curve decreasing, with no significant change in the RIII reflex threshold at any time after the injection. Thus, the mean RIII threshold, which was not significantly different at baseline between the parecoxib (7.8 ± 1 mA) and placebo (7.0 ± 0.7 mA) groups, was not significantly altered 60 minutes after treatment (7.5 ± 1.0 mA after parecoxib and 6.2 ± 0.6 mA after placebo). By contrast, the mean tolerance threshold (i.e. the maximum stimulus intensity on the recruitment curve), which was not significantly different at baseline between the parecoxib (14.3±2.7 mA) and placebo (15.0± 3.6 mA) groups, was significantly higher (p < 0.05) 40 and 60 minutes after administration of parecoxib (i.e. 17.2 ± 2.4 mA and 17.3 ± 2.0 mA) than after the placebo (14.1 ± 1.1 mA and 14.0 ± 1.3 mA).
Effects of parecoxib on the wind up phenomenon

As previously described\textsuperscript{25-26}, applying a series of 15 stimuli at 1.2 times the reflex threshold and at a frequency of 1 Hz, progressively increased the reflex responses (up to 250% of the first response). This wind-up of the RIII reflex, due to the temporal summation of nociceptive stimuli, was similar during the two control periods and did not significantly change after administration of the placebo or parecoxib (Fig 4). Consistent with these electrophysiological results, the progressive increase in pain sensation during the application of high frequency stimulation was similar in the two treatment groups at baseline (VAS score increased from 21.6±8 to 52 ± 12 in the parecoxib group and from 23.6±11 mm to 49± 15 in the placebo group) and was not significantly different after administration of parecoxib or placebo.
4. Discussion

The systemic administration of a clinically active dose of parecoxib significantly reduced the nociceptive flexion RIII reflex in healthy volunteers. This shows that COX-2 inhibitors act centrally and that the spinal transmission of nociceptive signals is affected by constitutively expressed COX-2 in the central nervous system. More generally, our results indicate that the anti-inflammatory and anti-nociceptive actions of COX-2 inhibitors are not necessarily related.

NSAIDs have long been suspected to affect the CNS\textsuperscript{29} as numerous animals studies over the last fifteen years have suggested\textsuperscript{2,13}. The finding that both COX isoenzymes are expressed in the CNS, that COX-2 is overexpressed in CNS neurons after peripheral inflammation, whereas COX-1 is overexpressed in the microglia\textsuperscript{30}, and that PG, which are released in the spinal cord during nociceptive stimuli, could facilitate central nociceptive transmission strongly support this idea\textsuperscript{2,4,13,31}. These results challenged the classical notion that the antinociceptive action of NSAIDs was due to a reduction of nociceceptor sensitisation. However, the peripheral and central modes of NSAIDs actions should not be considered as mutually exclusive but as complementary and possibly synergistic. In addition, the fact that COX-2 is also constitutively expressed in the CNS suggests that it could have a role in normal physiological pain (i.e. without inflammation).

These hypotheses were based mostly on animal data since few studies were performed in humans. Investigation of the central effects of COX-2 inhibitors in humans has relied on the analysis of primary and secondary hyperalgesia induced by cutaneous UV-B irradiation injury\textsuperscript{15}, electrical stimulation\textsuperscript{14} or capsaicin application\textsuperscript{16}. However, these models allow only an indirect approach to the central analgesics effects of treatment. In addition, the results seem to depend on the type of experimental pain
models since negative results were reported with the capsaicin model\textsuperscript{16}. Our data based on recordings of the nociceptive flexion RIII reflex which represents an objective and quantifiable electrophysiological correlate of the spinal transmission of nociceptive signals, show more directly the central action of COX-2 inhibitors. This methodology is particularly interesting as the cutaneous electrical stimulation of the sural nerve at the ankle bypasses the peripheral nociceptor. Thus, changes in the RIII reflex after administration of pharmacological agents, which do not act on the nerve conduction or muscular contraction, can be attributed to a central action of the drug. This methodology allows analysis of the pharmacological effects on the pain threshold and also over a wide range of supra-threshold stimulus intensities. The central effects of various mixed COX-1/COX-2 inhibitors (ketoprofen, ibuprofen, indomethacin) have been confirmed in healthy volunteers using this methodology\textsuperscript{21-23}. Our finding that a more selective COX-2 inhibitor modulates the RIII reflex, complements these results and suggests that the central action of conventional NSAIDs involves the inhibition of central COX-2. This result, however, does not exclude that central COX-1 has also a role in analgesia, as suggested by experimental studies\textsuperscript{30,32}.

The preferential effects of parecoxib on the RIII reflex recruitment curve (i.e. intensity-response) may indicate that it more specifically acts on the "gain" of nociceptive signal transmission in the spinal cord. Consistent with this, COX-2 has been shown to be the predominant constitutive isoform expressed in the central nervous system and particularly in the spinal cord\textsuperscript{12,13}. In accordance with electrophysiological and behavioral data in animals\textsuperscript{13}, our results indicate that constitutive COX-2 and probably prostaglandins are involved in normal nociceptive processing in humans. However, since in our study parecoxib was injected intravenously, we cannot exclude that it also acts supraspinally and the modulation of the RIII reflex involved descending controls.
Interestingly, Willer et al.\textsuperscript{33} showed that the effects of ketoprofen on the RIII reflex were reduced in paraplegic patients with a complete spinal cord transection, suggesting that mixed inhibitors could act supraspinally.

A series of animal studies have suggested that COX2 and prostaglandins, especially PGE2, are involved in central sensitisation (i.e. hyperexcitability of spinal nociceptive neurons) and hyperalgesia developing after peripheral inflammation and probably also nerve injury\textsuperscript{2,30,32,34,35}. The fact that COX-2 inhibitors reduced secondary hyperalgesia also suggest an action on central sensitization\textsuperscript{14,15}. In the present study, we investigated the effects of parecoxib on the progressive increase (i.e. "wind-up") of the RIII reflex induced by the temporal summation of the nociceptive inputs, which may be related to central sensitisation\textsuperscript{24,36}. Consistent with the results of animal studies, it has been shown previously, in humans, that the wind-up of the RIII reflex involves activation of N-methyl-D-aspartate (NMDA) receptors, since it is selectively reduced by low doses of ketamine\textsuperscript{25}. In the present study, the wind-up phenomenon was not altered by parecoxib. This is consistent with the results of animal electrophysiological studies of the effects of NSAIDs on wind-up\textsuperscript{37,38}, although contradictory results have also been reported\textsuperscript{39}. In any case, the opposite effects of parecoxib and ketamine on wind-up of the RIII reflex suggest that NMDA and COX-2 play different roles in the central nociceptive mechanisms.

In conclusion, our results provide the first electrophysiological experimental evidence showing that constitutive COX-2 can modulate central nociceptive processes in humans independent of peripheral inflammation. Thus, the development of centrally-acting COX-2 inhibitors may be of interest in the treatment of pain. The present study also shows that recordings of RIII reflex and analysis of its recruitment curve is a reliable experimental model for analysing the analgesics effects new COX-2 inhibitors.
