LS conceived and designed the study, undertook the analysis and interpretation of data, and wrote and finalized the manuscript. MR collected data and provided the statistical analysis. CP collected and analyzed the data. DB collected and analyzed the data. AM helped for revised manuscript. DC collected and analyzed the data. BM revised the manuscript. KB revised the manuscript and gave the final approval for publication.
ABSTRACT

Background: An aberrant right hepatic artery (ARHA) is a common anatomical variation. The risk associated with ARHA during pancreaticoduodenectomy (PD) continues to be debated. The aim of this study was to compare the clinical outcomes and survival after PD with ARHA against a matched cohort of patients without ARHA.

Methods: PD with an ARHA performed between January 2000 and September 2009 were retrospectively analyzed. Patients with an ARHA (group 1) were matched (1:2) to patients without an ARHA (group 2) according to gender, age, BMI, type of tumor and lymph nodes status. Peri- and postoperative outcomes were compared between the 2 groups. Overall (OS) and disease free (DFS) survival were estimated by Kaplan-Meier method and compared with Log-rank test.

Results: A total of 29 patients (group 1) and 55 patients (group 2) were compared. In group 1, an AHRA entered the tumor in 6 cases (20.7%), was sacrificed in 4 cases, and repaired in 2 cases. There was no difference regarding the rate of intraoperative and postoperative variables between the 2 groups. The oncological clearance (p=0.731) and survival (OS, p=0.843; DFS, p=0.832) were also similar.

Conclusions: Our study showed that the presence of an AHRA during PD was not associated with worse postoperative outcomes or survival.
INTRODUCTION

Pancreaticoduodenectomy (PD) remains the only curative treatment currently available for malignant diseases of the pancreatic head. Improvements in operative techniques and postoperative care have significantly decreased the mortality after PD within the last two decades in high-volume centers (1;2). The morbidity rates after PD remain high, reaching 30-50% (3;4). Morbidity is partly related to peri- and postoperative hemorrhage (5;6), which may be due to the highly variable arterial anatomy, particularly the anatomy of the hepatic artery (HA). These variations were fully described by Michels (7) from 200 autopsies and confirmed by Hiats et al. on 1000 liver donors (8). Among these anatomical variations, the Achilles heel during PD is the presence of an aberrant right hepatic artery (ARHA), including a replaced and accessory right hepatic artery, which is present in 10 to 18% of the population (8;9). ARHAs arise from the superior mesenteric artery (SMA), cross behind or through the head of the pancreas before skirting laterally or behind the portal vein, and finally penetrate the hepaticoduodenal ligament postero-laterally to the bile duct. It is imperative to look for the presence of an ARHA pre- and perioperatively to avoid its injury. When an AHRA is present, the challenge in peripancreatic malignant disease is the balance between its preservation and the need to achieve oncological clearance, which represents the only chance for prolonged survival. To date, few studies have evaluated the impact of the presence of an ARHA during PD in this difficult situation (10-13). These studies focused more on the management of ARHAs than on the impact that ARHAs have on recurrence and survival.

The aim of this study was to retrospectively analyze the outcomes and oncological results of PD in patients with ARHA when performed in a tertiary referral center. Particular attention was focused on the risk of an incomplete resection associated with the presence of ARHA.
METHODS

Patients

The study population included all of the consecutive PD for malignant disease that were performed at a single tertiary referral center between January 2000 and September 2009. The clinical data were retrospectively analyzed after retrieval from a prospectively collected PD database. Institutional Review Board approval was obtained for this study.

The collected data included age, sex, body mass index (BMI), tumor type, lymph node status, duration of surgery, venous or arterial resection and reconstruction, concomitant abdominal surgery, and transfusion needs. The postoperative complications of pancreatic fistula rates, classified into three groups (A, B, and C) according to the International Study Group of Pancreatic Fistula (ISGPF) criteria (14), and delayed gastric emptying (DGE) graded according to International Study Group of Pancreatic Surgery (ISPGS) criteria (15) were assessed. In this series, only pancreatic fistulas of grades B and C were considered because the nasogastric tube (NGT) was systematically left in place for 5 days. We also assessed postpancreatectomy hemorrhage, including intra- and extra-luminal bleeding according to the ISGPS definition; biliary fistula, defined as the presence of bile in the drainage fluid; and systemic infections, defined as the association of infectious signs with the need for systemic antibiotics. Perioperative mortality was defined as death during the initial hospital stay or within 30 days of surgery if the patient was discharged.

Surgery and Follow-up protocol

All patients underwent PD with an antrectomy and Child reconstruction. All of the procedures were performed by senior pancreatic surgeons, and a superior mesenteric artery first approach was performed systematically after 2006. In the last years of the study period, the decision to sacrifice or repair was based on the caliber of the artery, the presence or absence of a back flow from the distal part of the artery and the results of intraoperative liver
Doppler ultrasonography. Adjuvant chemotherapy was systematically administrated for patient with pancreatic adenocarcinoma with gemcitabine, whereas patients with distal bile duct cholangiocarcinoma had not. Regarding malignant ampulloma, only patients with positive lymph nodes involvement benefited from chemotherapy by FOLFOX or LV5FU2 regiments. After the resection, all patients were followed up every three months. A CT scan was performed every 3 months during the first 2 years and every six months thereafter. Follow-up data were obtained through routine clinic visits or through personal contact. The end of follow-up was set at August 1, 2012, or at the time of death.

Statistical analysis

To analyze the impact of the presence of ARHA during PD, the patients with an ARHA were identified by reviewing surgical reports (group 1) and were matched one-to-two with patients without an ARHA (group 2) from the PD database. The match was obtained according to age, sex, BMI, tumor type and lymph node status.

The quantitative variables were expressed as the mean ± standard deviation (SD) or the median value and compared using Student’s t-test or Wilcoxon test as appropriate. The qualitative variables were expressed as the mean ± SD and percentage and compared by Chi-squared or Fisher’s exact tests, as appropriate. The cumulative survival rates were estimated by the Kaplan-Meier method. The overall survival (OS) was calculated from the day of surgery to the date of death or the end of follow-up. Disease-free survival (DFS) was calculated using the date of death or recurrence as the time of the terminal event. The survival curves were compared by a log-rank test. A p value of < 0.05 was considered statistically significant. R statistical software, version 2.15.1 (http://www.r-project.org/), was used.
RESULTS

Demographic data and matched group

During the study period, 213 patients underwent PD with curative intent for malignant disease. Among these 213 patients, 29 (13.6%) had an ARHA (group 1), including 18 (62%) cases and 11 (38%) cases of type 6 (accessory RHA) and type 3 (replaced RHA) of the Michels classification, respectively. They were matched 1:2, and only 55 patients (group 2) of the 58 planned matches were found according to the matching criteria. The demographic data and histopathology features of the two groups are reported in table 1 and show great matching correlation.

In group 1, AHRA was diagnosed preoperatively by CT scan or angio-MRI (Figure 1A and 1B) or during surgery in 20 (69%) and 9 (31%) cases, respectively. No patient received preoperative embolization of the ARHA to prevent any possible complications related to intraoperative sacrifice. Among the 29 cases of ARHA, 23 (79.3%) were dissected free and preserved (figure 1C), whereas 6 crossed into the tumor (20.7%) and were either sacrificed in 4 cases or reconstructed in 2 cases (figure 2).

Perioperative data and outcomes

Peri- and postoperative outcomes of the two groups are provided in table 2. There were no significant differences between the 2 groups in terms of the surgical parameters, the postoperative outcome, or the extent of resection. No cases of liver failure, infarction, abscess or biliary fistula were found in group 1. The extent of resection and the histological feature of the 2 groups are provided in table 3 and show that the R0 rates were similar in the 2 groups (p=0.731)
Long-term survival

The mean global follow-up was 36 ± 36 months. The OS and DFS of the entire studied population are shown in figures 3A and 3B, respectively. The overall median survival time was 21.8 months in group 1 and 23.6 months in group 2, without significant intergroup differences (p=0.843). The median DFS was 11.2 in group 1 and 13.3 months in group 2 (p=0.832).
DISCUSSION

While several studies have examined the prognostic value of clinical and histological factors, including age, BMI, lymph node invasion, and margin thickness, few have evaluated the impact of anatomical variations, such as the presence of ARHA on the postoperative course of PD (10-13). This matched case-controlled study showed that the presence of an ARHA did not impact the perioperative complications or the oncological prognosis.

Although special attention was paid to determine the presence of an ARHA during preoperative explorations, a high percentage of ARHA was ignored until surgery. Indeed, about one-third of ARHAs were discovered perioperatively, a feature that has been described previously (12). Stauffer et al. reported a rate of preoperatively unknown ARHA of 64% (11). This finding emphasizes the need for standardization of imaging reports that mention the presence or absence of arterial anatomical variations prior to PD. This knowledge may allow for preoperative embolization to avoid perioperative hemorrhagic complications. Preoperative embolization favors the development of arterial collaterals to the liver, including the opening of intrahepatic shunts, which may prevent the risk of liver failure when an ARHA must be sacrificed (16). We never opted for this procedure which probably doesn’t decrease the risk of biliary anastomotic fistula. When an ARHA appears to be invaded preoperatively, neoadjuvant chemo-radiotherapy may be indicated to reduce the rate of incomplete resection with arterial preservation (12). To bridge the lack of relevance of imaging results, we suggest that all PD begin through a SMA right first approach with dissection to free the first 3 centimeters, where AHRAs mostly arise (17;18). From an oncological point of view, the SMA first approach (a right-to-left early retropancreatic dissection) may reduce the rate of an R1 or R2 resection.

This study also provided information regarding the management of ARHAs in patients with cancer of the pancreatic head. Although one-fifth of AHRAs crossed through the tumor, the vessel could be preserved in most cases, an observation that is in line with previous reports
(13;19) and which could explain the lack of significant differences between the 2 groups in our study.

In our series, 4 small caliber ARHA were sacrificed without relevant postoperative consequences. Unfortunately, we have little information about the decision to sacrifice or reconstruct the ARHA, especially concerning the back-flow from the distal part in the cases where arteries were sacrificed. To date, no report about the cut-off caliber from which ARHA might be repaired has been published. When the main hepatic artery arises from the SMA (type 9 of Michel's classification), it must be repaired (17). We learned from liver transplantation techniques that when an ARHA reconstruction is necessary, the easiest way to do so is to bridge the ARHA in the stump of the gastro-duodenal artery (GDA). After PD, the GDA stump is frequently not usable, and the ARHA can be reimplanted in the splenic artery end-to-end or end-to-side using a saphenous vein jump graft.

One bias in our study is that all PD were performed by senior surgeons with a large amount of experience in liver transplantation and a routine level of experience in arterial hepatic dissection and reconstruction, which may have reduced the postoperative morbidity and the incidence of R1 or R2 resections. Performing intraoperative liver Doppler ultrasonography is recommended to ensure the results of the arterial sacrifice or reconstruction and to prevent postoperative complications (20;21). We believe that surgical expertise is a key point in pancreatic surgery to reduce morbidity and improve survival, and these patients should be managed in high-volume centers (1;2;22).

In conclusion, this matched case-controlled study showed that the presence of an AHRA during PD for malignant disease was not associated with an increased rate of postoperative complications or reduced OS or DFS. Patients requiring PD should be referred to upper GI surgical centers where digestive arterial reconstructions are routinely performed. This improves the safety of complex pancreatic surgery without jeopardizing the oncological prognosis.
