Abstract

Whereas agonists bind directly in the heptahelical domain (HD) of most class-I rhodopsin-like G-protein coupled receptors (GPCRs), class-III agonists bind in the extracellular domain of their receptors. Indeed, the latter possess a large extracellular domain composed of a cysteine-rich domain and a venus flytrap module (VFTM). Both the low sequence homology and the structural organization of class-III GPCRs raised the question of whether or not the HD of these receptors functions the same way as rhodopsin-like GPCRs. Here we show that the HD of metabotropic glutamate receptor 5 (mGlu₅) displays the same agonist-independent constitutive activity as the wild-type receptor. Moreover, we show that the non-competitive antagonist MPEP and the positive allosteric modulator DFB act as inverse agonist and full agonist, respectively, on the mGlu₅ HD in the absence of the extracellular domain. This illustrates that, like rhodopsin-like receptors, the HD of mGluRs can constitutively couple to G-proteins, and be negatively and positively regulated by ligands. These data show that the HD of mGluRs behave like any other class-I GPCRs in terms of G-protein coupling and regulation by various types of ligands.

Introduction

G-protein coupled receptors (GPCRs) represent more than 1% of the total mammalian genes. They have been successful during animal evolution to recognize a wide range of stimuli from photon to large glycoproteins (1-3). These receptors transduce the extracellular signals in cellular responses via heterotrimeric G proteins. On the basis of sequence similarity, mammalian GPCRs have been classified into five major classes (3), but all share a common central domain composed of seven transmembrane helices, the heptahelical domain (HD). This domain is assumed to adopt various active and inactive conformations, the former being stabilized by agonists while the latter are stabilized by inverse agonists (4, 5). In most cases, these ligands directly interact in the heptahelical domain, but agonists can act within an additional extracellular domain (1, 6). This is the case of class-III GPCRs (7-10).

Class-III GPCRs include receptors for the main neurotransmitters glutamate and GABA as well as receptors for Ca^{2+} , sweet taste compounds and pheromones (10). Their agonist binding domain is homologous to bacterial periplasmic binding proteins involved in the trafficking of ions, amino-acids and sugars in the periplasm of gram-negative bacteria (7, 10, 11). This was confirmed by the determination of the crystal structure of the mGlu₁ extracellular domain. This domain has a bilobate structure that adopts a closed conformation upon agonist binding in the cleft that separates both lobes (12, 13), and is often called a "Venus flytrap" module (VFTM).

How agonist binding in the VFTM leads to the activation of the HD remains unknown. However, the determination of the crystal structure of the mGlu₁ VFTM with and without bound glutamate together with the demonstration that these receptors are constitutive dimers (14, 15) lead to a model for activation of class-III GPCRs (10, 12, 16). Accordingly, agonist binding in at least one VFTM of these dimeric receptors leads to a large conformational change of the dimer of VFTMs, possibly forcing the two HDs to interact with each other differently. This is expected to stabilize their active state. Such a peculiar structural organization of the receptor protein, associated with a very low sequence identity of their HD compared to that of other GPCRs, raised the question of whether or not the HDs of all GPCRs function the same way.

We previously reported that mGlu_{1a} and mGlu₅ metabotropic glutamate receptors (mGluRs) display constitutive activity (17, 18). A precise analysis of the constitutive activity of these receptors led us to propose that it resulted from a spontaneous activity of their HD rather than from a spontaneous closure of their VFTM (19). In agreement with this proposal, the non-competitive antagonists, MPEP and BAY36-7620, which bind in the HD (20, 21) are the only antagonists that display inverse agonist activity.

In the present study we examined whether the HD of such receptors could activate G-proteins in the absence of the VFTM. We found that mGlu₅ HD was able to spontaneously activate Gq-type G-proteins, and that this constitutive activity could be inhibited by the known mGlu₅ inverse agonist. Of interest, the positive modulator of mGlu₅ receptor, although devoid of agonist activity on the wild-type receptor, acted as a full agonist on mGlu₅ HD in the absence of the large extracellular domain. In summary, we provide novel insight on the mechanism of action of negative and positive allosteric modulators of class-III GPCRs. Moreover, our data show that the HD of class-III GPCRs displays constitutive activity and can be positively or negatively regulated by ligands, like any other class-I GPCRs.

Materials and methods

Materials

Glutamic acid was purchased from Sigma. L-Quisqualic acid and MPEP (2-methyl-6-(phenylethynyl)-pyridine) hydrochloride were purchased from Tocris Cookson (Bristol; UK). Glutamate-pyruvate transaminase (GPT) was purchased from Roche (Basel, Switzerland). Culture medium, foetal calf serum (FCS) and other products used for cell culture were purchased from GIBCO-BRL-Life Technologies, Inc. (Cergy Pontoise, France). [³H]myo-inositol (23.4 Ci/mol) was purchased from Amersham (Saclay, France).

Construction of mGlu₅ mutants

The construction of the N-terminal HA-tagged rat mGlu_{5a}, pRK5a-NHA, has been already described (22). The plasmid expressing the Δ5 mutant was obtained by inserting between the Mlu-I and Xba-I sites of pRK5-NHA, the mGlu_{5a} cDNA coding for the HD and the C-terminal tail between the residues P568 and the C terminal end obtained by PCR. The final plasmid encodes for a protein possessing the signal peptide of mGlu₅ followed by a HA tag and then by the HD and the intracellular C terminus of mGlu_{5a}. The same strategy was used to generate Δ5Δ that corresponds to the mGlu_{5a} HD segment between P568 and L864 (Fig. 1A).

Cell culture and transfection

HEK293 cells were cultured in Dulbecco's modified Eagle's medium supplemented with 10% FCS and transfected by electroporation as described elsewhere (23). Ten million cells were transfected with plasmid DNA encoding mGlu₅ (0.6 μg), Δ5 (5 μg), Δ5Δ (5 μg) and completed to a total amount of 10 μg plasmid DNA with pRK6. To avoid any influence of glutamate in the assay medium released by the cells, the high affinity glutamate transporter EAAC1 was also co-transfected with the receptor.

Synthesis of 3,3'-difluorobenzaldazine (DFB)

3,3'-difluorobenzaldazine DFB was synthesized according to Buu-Hoi and Saint-Ruf (24).

Immunofluorescence

Immunofluorescence assay was carried out as described elsewhere (22). Briefly, 24 hours after transfection, cells plated on coverslips were washed with PBS and incubated for 90 minutes at 37°C with an anti-HA mouse monoclonal antibody (clone 12CA5; Roche, Basel, Switzerland) at 1.33 µg/mL in PBS and 0.2% gelatine. The primary antibody was then detected with a Cy3 secondary antibody (1 µg/mL) (Jackson ImmunoResearch, West Grove, PA). Coverslips were mounted and observed using a Axiophot2 microscope (Zeiss, LePecq, France).

Cell surface quantification by ELISA

Twenty four hours after transfection, cells were washed twice with PBS, fixed with PBS and 4% paraformaldehyde and incubated for 30 minutes with an anti-HA rat monoclonal antibody (clone 3F10; Roche, Basel, Switzerland) (0.5 µg/mL) in PBS containing 5% FCS. Cells were then incubated with a secondary goat antibody conjugated to peroxydase (Jackson ImmunoResearch, West Grove, PA) (1 µg/mL). Secondary antibody was detected and quantified by chemiluminescence using Supersignal West Femto (Pierce, Rockford, IL) and a Wallac Victor² luminescence counter (Molecular devices, St Gregoire, France).

Inositol phosphate determination

Inositol phosphate (IP) accumulation in transfected cells was performed in 96-well microplates after cell labeling overnight with [³H]myo-inositol. The IP formation determination was performed after a 30 minutes incubation in the presence of 10 mM LiCl and in the presence or absence of the indicated compounds. For basal determination of IP production, GPT (1U/ml) and 2 mM pyruvate were added to the reaction. The reaction was stopped with 0.1 M formic acid. Supernatants were recovered and IP produced were purified in 96 well plates by ion exchange chromatography using DOWEX resin. Radioactivity was measured using a Wallac 1450 MicroBeta microplate liquid scintillation counter (Molecular devices, St Gregoire, France). Results are expressed as the amount of IP produced over the radioactivity present in the 10% triton X100 and 0.1 N NaOH-solubized membrane fraction, plus the produced IP. The dose-response curves were fitted using the GraphPad Prism program and the following equation:

$$y = ((y_{\max} - y_{\min}) / (1 + (x / EC_{50})^n)) + y_{\min}$$

Intracellular calcium measurements

Cells were seeded after transfection in poly-ornithine coated black-walled, clear bottom 96-well plates and cultured for 24 hours. Cells were washed with freshly prepared buffer and loaded with 1 μM Ca^{2+} -sensitive fluorescent dye Fluo-4AM (Molecular Probes, Leiden, The Netherlands) for 1 hour at 37°C. Cells were washed and incubated with 50 μL of buffer. A drug plate was prepared with the various concentrations of agonist to be tested and 50 μL of 2x-drug solution was added in each well after 20 seconds of recording. Fluorescence signals (excitation 485 nm, emission 525 nm) were measured using the fluorescence microplate reader Flexstation (Molecular devices, St Gregoire, France) at sampling intervals of 1.5 second for 60 seconds.

All data represented correspond to means \pm SEM from representative experiments performed in triplicate.

Results

Expression of wild-type and truncated mGlu₅ receptors

To study the functional properties of mGlu₅ HD, two truncated constructs were created. The first one, $\Delta 5$, was obtained by removing the VFTM and the cysteine-rich domain, and the second, $\Delta 5\Delta$, was generated by truncating most of the C-terminal tail of $\Delta 5$ (Fig. 1A). Both N-terminal HA-tagged truncated mutants were expressed at the cell surface as shown by immunostaining of non-permeabilized cells (Fig. 1B). Under the same conditions, no fluorescence signal was detected at the surface of control cells transfected with the N-terminal HA-tagged GABA_{B1} subunit of the GABA_B receptor that cannot reach the cell surface alone (25, 26) or with an empty pRK6 plasmid (not shown).

Surface expression of the HA-tagged mGlu₅, $\Delta 5$ and $\Delta 5\Delta$ was then quantified using an ELISA assay. These experiments revealed that, for an equal quantity of plasmid DNA transfected in HEK293 cells, the two truncated mutants were 5 to 10 times less expressed at the cell surface than wild-type receptor (not shown). In order to compare the functional properties of these constructs, conditions were set up to achieve a similar surface expression level as depicted in Fig. 1C.

mGlu₅, truncated mutants are constitutively active

The G-protein coupling activity of mGlu₅, $\Delta 5$ and $\Delta 5\Delta$ was examined by measuring IP accumulation. We found a higher IP formation in cells expressing any of these three constructs compared to mock-transfected cells (Fig. 2A). This basal activity represented 291, 211 and 284% of the control IP production, for mGlu₅, $\Delta 5$ and $\Delta 5\Delta$, respectively. Among these three constructs, only the wild-type mGlu₅ could be stimulated by glutamate (Fig. 2A). Even when applied at high concentration (up to 10 mM, not shown), glutamate had no effect on the truncated mutants (Fig. 2A). These data show that the removal of the large extracellular domain suppresses the ability of glutamate to activate the receptor, but does not prevent the truncated constructs to activate G-proteins spontaneously.

As mentioned above, the truncated receptors did not reach efficiently the cell surface, and accumulated in the ER. Therefore, it is possible that the observed high basal IP formation was due to the intracellular accumulation of mGlu₅ receptors

rather than to a constitutive activity of the receptor at the cell surface. However we found that a longer version of $\Delta 5\Delta$ with 6 additional residues at the C-terminal end did not reach the cell surface and accumulated in the ER as shown by immunofluorescence studies and ELISA assays performed on intact and permeabilized cells (data not shown). No high basal IP formation could be measured in cells expressing this construct (data not shown). The same was true for a mGlu₅ chimeric construct bearing the ER retention signal of the GABA_{B1} receptor subunit (data not shown). This confirmed that the basal activity measured was mostly generated by receptors at the cell surface.

Constitutive activity of D5 and D5D is inhibited by a negative allosteric modulator

The non-competitive antagonist MPEP binds within the HD of mGlu₅ (20, 27). This compound, often called a negative allosteric modulator, also inhibits the constitutive activity of mGlu₅. As observed on the wild-type receptor ($48.2 \pm 15.1\%$ inhibition, $n=8$), MPEP also inhibited $42.8 \pm 1.5\%$ ($n=3$) and $46.7 \pm 15.3\%$ ($n=7$) of the basal IP formation measured in cells expressing $\Delta 5$ and $\Delta 5\Delta$, respectively (Fig. 2B). These effects of MPEP were dose-dependent with IC₅₀ values determined on $\Delta 5$ (7.6 ± 6.6 nM, $n=3$, not shown) or $\Delta 5\Delta$ (10.4 ± 6.6 nM, $n=7$) similar to that determined on mGlu₅ (8.1 ± 4.3 nM, $n=8$) (Fig. 2B). These data confirm that basal IP formation measured in cells expressing $\Delta 5$ or $\Delta 5\Delta$ originates from a constitutive PLC activation by these constructs, and that MPEP does not require the extracellular domain of mGlu₅ to interact with the receptor and acts as an inverse agonist. Furthermore, these data confirm the correct folding of the mGlu₅ HD in the absence of both the large extracellular domain and the long C-terminal tail.

In contrast to the wild-type receptor, the truncated mutants are activated by a positive allosteric modulator

Recently, positive allosteric modulators of various mGlu receptors have been identified (10, 28, 29). Such compounds display no or very low agonist activity, but largely potentiate the action of agonists interacting in the VFTM. Analysis of the putative binding site of the mGlu₁ and mGlu₂ modulators suggested that they bind in the HD of these receptors (29, 30). Very recently, DFB has been reported as a positive allosteric modulator of mGlu₅ (31). In agreement with this study, we found

that DFB did not activate mGlu₅ receptor when care was taken to remove as much as possible glutamate from the medium (Fig. 3). However, DFB potentiated the action of glutamate, decreasing its EC₅₀ value 2 fold (32.2 ± 9.2 (n=9) to 17.4 ± 4.4 μ M (n=4) in the absence and presence of 100 μ M DFB, respectively) (Fig. 3A). The same effect was observed with the agonist quisqualate (EC₅₀ 23.1 ± 2.3 (n=5) and 13.1 ± 5.5 nM (n=3) in the absence and presence of DFB, respectively, data not illustrated). The maximal effect of glutamate was however not modified by DFB. As shown in Fig.3B, DFB potentiated quisqualate-induced activation of mGlu₅ with an EC₅₀ value of 11.3 ± 1.4 μ M. A similar effect of DFB was observed when the Ca²⁺ signal was measured in cells expressing mGlu₅ (Fig. 3A).

The effect of DFB was then examined on the truncated receptors $\Delta 5$ and $\Delta 5\Delta$. In contrast to what was observed with the wild-type receptor, DFB activated directly these constructs (Fig. 4A). This effect was dose-dependent with an EC₅₀ value of 12.9 ± 6.3 μ M (n=6)(Fig. 4A) identical to that measured for the potentiating effect on the wild-type receptor (Fig. 3A). A similar effect was obtained with $\Delta 5$ (data not shown). DFB was also able to induce a Ca²⁺ signal in cells expressing $\Delta 5$ or $\Delta 5\Delta$ (Fig. 4B) with EC₅₀ values of 20.2 ± 1.7 μ M and 19.6 ± 1.2 μ M, respectively. These data indicate that whereas DFB is a clear positive allosteric modulator devoid of agonist activity on mGlu₅, it acts as an agonist on the truncated receptors.

DFB-induced activity of $\Delta 5\Delta$ is close to the agonist-induced activity of mGlu₅

In order to compare the activities of mGlu₅ and $\Delta 5\Delta$, cell surface expression and basal and agonist-induced IP production were measured in cells transfected with various amounts of plasmid DNA. Both basal and glutamate-induced IP productions were directly proportional to the amount of receptors at the cell surface, the slope of the correlation lines being indicative of the specific (amount of IP produced per receptor) basal and glutamate-induced activity of the receptor (Fig. 4C). When the same analysis was performed with $\Delta 5\Delta$ in the absence and presence of DFB, the same correlation lines were obtained, showing that the specific constitutive activity of $\Delta 5\Delta$ is similar to that of mGlu₅, and that DFB-induced activity of $\Delta 5\Delta$ is similar to the glutamate-induced activity of the wild-type receptor (Fig. 4C).

Inhibition of the DFB-induced response of D5D by MPEP

Since both DFB and MPEP were found to act on $\delta 5$, we examined whether MPEP could inhibit the action of DFB. As shown in Fig. 5, MPEP inhibited the effect of DFB on IP production or increase in intracellular Ca^{2+} in cells expressing $\delta 5$. However, even at high concentration, MPEP only partly inhibited the effect of DFB on $\Delta 5\Delta$. This indicates a complex interaction between MPEP and DFB binding sites, in agreement with the partial inhibition of [^3H]-methoxyPEPy (an analog of MPEP) binding by DFB on the wild-type receptor (31).

Discussion

The present study demonstrates that mGlu₅ HD can activate PLC in the absence of both the large extracellular domain (the VFTM and the cysteine-rich domain) and the long C-terminal intracellular tail. Indeed, this domain of the mGlu₅ receptor displays a similar constitutive activity as the wild-type receptor. Moreover, we show that the inverse agonist MPEP conserved its activity on this truncated mutant. Finally, our data demonstrate that the positive allosteric modulator DFB is acting as a full agonist on this domain. These data shed light on the possible mechanism of action of such positive allosteric modulators of class-III GPCRs.

Our data clearly indicate that both the inverse agonist MPEP, and the positive allosteric regulator DFB do not need the large extracellular domain of mGlu₅ to exert their action. Indeed, our data indicate that they directly interact within the HD of this receptor, therefore at a site distinct from the orthosteric ligand binding site located in the VFTM (10, 12). This is in agreement with the proposed binding site of the non-competitive antagonists of mGlu₅ (MPEP) (20, 27), and mGlu₁ (21, 30, 32). Of interest, when a detailed analysis of these antagonists binding sites have been performed by site directed mutagenesis and molecular modeling, the binding pocket was found to be equivalent to that of retinal in rhodopsin (20, 27, 30). Although positive modulators of mGlu receptors have been identified only recently (28, 29, 31), one study analyzed the binding site of the mGlu₂ potentiator LY487379 (29). In that case again, the binding pocket was found to be located within the HD, with important residues located in TM IV and V. In agreement with the latter study, our data also indicate the positive modulator DFB binds in the HD of mGlu₅. However, the effect of DFB was not fully inhibited by MPEP in agreement with the reported partial inhibition of MPEP binding by DFB (31). This indicates a complex interaction between these two ligands suggesting they act at different sites. This reinforces the need for a detailed analysis of the DFB site.

Group-I mGluRs, mGlu_{1a}, mGlu_{5a} and mGlu_{5b} display constitutive activity in heterologous expression systems (17, 18). The absence of inverse agonist activity of competitive antagonists known to prevent VFTM closure lead us to propose that the constitutive activity originates from the HD able to reach an active state even if the VFTM stays open (19, 21). In agreement with this possibility, non-competitive

antagonists interacting in the HD have inverse agonist activity (20, 21). Our present data showing the HD of mGlu₅ displays the same constitutive activity as the wild-type receptor strongly support this idea. A kinetic model recently developed also confirmed this idea and, of interest, showed that the allosteric coupling between the VFTM and the HD is not strict (19). In other words, the change in conformation of one domain only influences the equilibrium constant between the two states of the other domain, but does not force it to adopt a specific conformation. Such a finding is likely of importance since we recently reported that the constitutive activity of group-I mGluRs is tightly regulated by the intracellular proteins Homer in neurons (33). As such, group-I mGluRs can be activated either by extracellular glutamate or by the intracellular protein Homer1a. The low allosteric coupling between the HD and the VFTM allows the intracellular protein Homer1a not to increase dramatically glutamate affinity. Thus, the receptor can retain its ability to be further activated by extracellular glutamate in a physiological range of concentration (19).

Our data confirm that the positive allosteric modulator of mGlu₅, DFB is devoid of agonist activity on the wild-type receptor (it is not able to activate the full length receptor by itself) (31). We previously proposed that such a ligand is not able to directly stabilize the active state of the HD, but instead facilitates the active closed state of the VFTM to activate it (19). This proposal is clearly not consistent with our present data showing DFB activates the HD expressed alone to a similar extent as glutamate on the full length receptor. Accordingly, it appears that the presence of the VFTM prevents DFB from activating the HD, a conclusion not consistent with a weak allosteric coupling between the VFTM and the HD. How can one reconcile these observations? Recent findings revealed GPCRs likely exist in at least 3 states, a R_g (ground) state that corresponds to the totally inactive state stabilized by inverse agonists, a R state that is able to activate G-proteins though with a low efficacy, and a R* state that corresponds to the active state of the receptor stabilized by full agonists (34, 35). By analogy, we propose the HD of mGlu₅ also exists in these 3 states: HD_g, HD and HD*. The equilibrium between HD_g and HD may not be controlled by the VFTM. This equilibrium would be at the origin of the observed constitutive activity not inhibited by competitive antagonists, but by non-competitive ones directly acting in the HD (Fig. 6). In contrast, the HD* state would require the VFTM to be in the active state, such that DFB would not be able to activate the receptor without agonists. In contrast, in the absence of VFTM, the HD would be able

to reach more freely the fully active state HD* in the presence of DFB (Fig. 6). Since mGluRs are constitutive dimers, it is possible that the HD can oscillate between HDg and HD states when the dimer of VFTMs is in the resting orientation (R in Fig. 6). On the other hand, when the dimer of VFTMs is in the active orientation (A in Fig. 6), the HD can reach the HD* state that is stabilized by DFB. Accordingly, it is possible that the formation of a specific form of the HD dimer is stabilized by DFB. However, further experiments are required to confirm this proposal.

The periplasmic binding proteins are known to bind their ligand in the periplasmic space and to deliver it to a transmembrane complex responsible for the transport of the molecule inside the bacteria (11, 36). Among the hypotheses for the activation mechanism of class-III GPCRs, it was proposed that the VFTM would bind the ligand and deliver it to another site within the HD leading to its activation (37). Our data show that the mGlu₅ HD cannot be activated by glutamate up to a concentration of 10 mM. This is not due to the inability of this domain to be activated since DFB can fully activate this domain. Such an observation favors therefore the second proposal that originates from the crystal structure of the mGlu₁ VFTM (10, 12, 16). Indeed, this domain forms dimers and a large change in conformation of the dimer is observed upon agonist binding (Fig. 6). This is assumed to stabilize a specific conformation of the dimer of associated HDs leading to their activation (Fig. 6). As mentioned above, class-III VFTMs are not only involved in ligand binding but also in the dimerization process of these receptors (14, 15, 38). Such a dimer formation is assumed to be crucial for the intramolecular transduction between the VFTM and the HD (10). Whether dimerization of GPCRs is required for G-protein activation is still a matter of intense debate (39-42). At least our data show that the stabilization (and even disulfide cross-linking between the subunits) of class-III dimers by the VFTM is not required for the HD to activate G-proteins. Accordingly, either the HD can dimerize by itself, or dimerization is not required for G-protein activation.

There is actually a lot of pharmaceutical interests in identifying new allosteric modulators of mGluRs as potential new therapeutic agents. Our data show that the use of the HD of mGluRs may be a good tool to identify such new ligands since an agonist rather than a positive modulator has to be identified. The group of Conklin also highlighted the potential use of receptor activated solely by synthetic ligands (RASSL) (43). HDs of mGluRs may constitute new possibilities to develop such tools

that can be targeted in specific neuronal compartment not attainable with other mutant GPCRs.

Figure legends

Figure 1. Cell surface expression of mGlu₅, D5 and D5D.

A. Schematic representation of mGlu₅, Δ5 and Δ5Δ and location of the sites of truncation. VFTM stands for venus flytrap module, CRD for cysteine-rich domain and HD for heptahelical domain. The white box represents the HA tag and the grey box corresponds to the signal peptide of mGlu₅. **B.** Surface expression of mGlu₅, Δ5 and Δ5Δ in HEK 293 cells was detected by immunofluorescence on non permeabilized cells. **C.** Quantification of cell surface expression of mGlu₅, Δ5 and Δ5Δ by ELISA on intact cells. Cells were transfected with 0.6, 5 and 5 μg of plasmids expressing mGlu₅, Δ5 and Δ5Δ, respectively.

Figure 2. Like mGlu₅, D5 and D5D are constitutively active.

A. IP production measured in mGlu₅, Δ5 and Δ5Δ or mock transfected HEK 293 cells under basal conditions (white bars) or in the presence of 1 mM Glu (black bars). Basal IP formation in mock-transfected cell is highlighted by a dotted line. Data corresponds to the ratio between total IP produced by the cells and the total radioactivity remaining in the membranes plus the produced IPs. **B.** MPEP decreased the basal IP production in HEK293 cells expressing mGlu₅ (open circles) and Δ5Δ receptors (closed circles). Results are expressed as the percentage of the basal IP production measured in the absence of MPEP.

Figure 3. DFB potentiates agonist-induced activity of wild-type mGlu₅.

A. Effect of increasing concentrations of glutamate in the absence (CTR, open circles) or presence (DFB, closed circles) of 100 μ M DFB on IP production in cells expressing mGlu₅. **B.** Effect of increasing concentration of DFB was measured on cells expressing mGlu₅ in the absence (open circles) or presence of 10 nM quisqualate (black circles). **Insert:** the effect of 10 nM quisqualate on intracellular Ca²⁺ concentration was measured under control condition (C) or in the presence of 100 μ M DFB (DFB). Vertical bar represents a change in the fluorescence signal of 1000 units. Data are expressed as the percentage of the maximal effect measured with quisqualate plus DFB.

Figure 4. Direct activation of D5D by the positive allosteric regulator DFB.

A. Effect of increasing doses of DFB on Δ 5 Δ . DFB dose-dependently activates the truncated receptor Δ 5 Δ . The curve has been normalized such that the basal response is zero and the maximum is 100 %. **Insert:** IP formation (% above the basal) was induced by DFB only in cells expressing Δ 5 Δ and not in cells expressing mGlu₅. **B.** Direct stimulation of Δ 5 and Δ 5 Δ by 100 μ M DFB as revealed by intracellular Ca²⁺ measurement with Fluo-4. **C.** Activity of mGlu₅ (squares) and Δ 5 Δ (circles) as a function of their membrane expression. Cells were transfected with increasing amounts of cDNA coding for these receptors and surface expression of mGlu₅ and Δ 5 Δ was measured by ELISA on intact cells. Basal (open symbols) and glutamate (1 mM) or DFB (1 mM) (closed symbols) induced IP formation were measured in parallel.

Figure 5. MPEP inhibits partially DFB-induced activity on D5D.

A. Effect of 10, 30 and 100nM MPEP on IP production induced by 300 μ M DFB in cells expressing Δ 5 Δ . **B.** Effect of 10 and 100nM MPEP on intracellular Ca²⁺ release induced by 300 μ M DFB on cells expressing Δ 5 Δ .

Figure 6. Schematic representation of the possible action of inverse agonists and positive modulators of mGlu₅ receptor.

Top: the constitutive dimer of mGlu₅ is shown to be composed of a VFTM (top), a cystein-rich domain (middle) and a HD. The HD is proposed to oscillate between a

slightly active state (HD) and a totally inactive ground state (HDg), the latter being stabilized by inverse agonist. This equilibrium can occur even though the dimer of VFTM stays in the resting state (R). The dimer of VFTMs is assumed to reach an active orientation (A) in the presence of agonist, leading to the stabilization of a fully active state of the dimer of HDs (HD*). The positive allosteric modulator, DFB, is proposed to bind with a higher affinity on HD*, stabilizing the fully active state of the receptor, leading to an increased affinity of the receptor for agonists (19). Bottom: in the absence of the large extracellular domain, the HD can reach more freely the fully active state HD* allowing the positive modulators to act as full agonists.
