Localization of calcium and microfilament changes in mechanically stressed cells

Marianne Horoyan, Anne-Marie Benoiel, Christian Capo and Pierre Bongrand¹

Laboratoire d'Immunologie, Hôpital de Sainte-Marguerite, B.P. 29, 13277 MARSEILLE Cedex 09, FRANCE

We combined fluorescence labeling, digital image processing, and micromanipulation to investigate the intracellular events induced by inflicting a mechanical stress on rat basophilic leukaemia cells. Our findings are as follows: *i*) Most cells displayed a localized calcium rise in response to micropipette aspiration. This represented an average threefold increase as compared to resting level and it was observed during the first ten seconds following aspiration. A slow return to initial level occurred within about 3 minutes. Further, this calcium rise involved a mobilization of intracellular stores since it was not prevented by adding a calcium chelator into the extracellular medium. *ii*) All micropipette-aspirated cells displayed a local accumulation of microfilaments, with a preferential localization in the cell protrusions or near the pipette tips. *iii*) No absolute correlation was found between the localization of calcium rise and cytoskeletal accumulation. *iv*) Cell deformability was decreased when intracellular calcium was maintained at a constant (high or low) level with ionomycin and/or EGTA.

It is concluded that cells have a general ability to respond to mechanical stimulation by a coordinated set of events. More parameters must be studied before the mechanisms of cell shape regulation are fully understood.

Living cells have a basic capacity to change their shape and move through the surrounding milieu (1). It is an obvious requirement that these processes be regulated. For example, if a cell sends a large lamellipodium towards some region of interest, due to the finiteness of membrane area and constancy of cell volume (2), some negative signal must limit the protrusive activity in order to avoid useless loss of energy. Also, when a cell hits a solid obstacle, this encounter must be perceived in order to initiate a direction change, even if the foreign surface is not recognized by specific membrane receptors. Finally, in multicellular organisms, it is necessary that the components of tissues endowed with a mechanical function be able to respond to exogeneous forces : thus, it is well known that arterial walls can modify their tension in response to variations of the blood pressure.

It is therefore not surprising that many authors reported on the ability of various cells to respond to mechanical stimulation. The migratory activity of isolated corneal cells was enhanced by the application of tension (3). Mechanical loading of chicken chondrocytes increased DNA and glycosaminoglycan synthesis (4). Fluid shear forces were found to induce the formation of stress fibers in human endothelial cells (5). When blood leukocytes were sucked into glass micropipettes, they displayed erratic deformations of the mechanically induced protrusion within several tens of seconds (6). Finally, turbulent but not laminar shear stress increased the turnover of vascular endothelial cells in vitro (7).

However, the mechanisms by which mechanical stimuli generated diverse cell responses remain incompletely understood. Indeed, stretch-activated cationic channels were demonstrated in vascular endothelial cells (8, 9) or epithelial cells (10), but no direct link was demonstrated between ionic fluxes and modifications of cell behavior. In the present work, we took advantage of fluorescent labeling and digital image processing to localize calcium and microfilament changes in rat basophil leukaemia (RBL) cells subjected to mechanical aspiration in glass micropipettes. It is concluded that the imposed stress induced transient and local calcium rises with a participation of intracellular calcium stores, together with cytoskeletal changes. However, both events were not always spatially correlated, which strongly suggested that unidentified biochemical events were involved in cell responses.

MATERIALS AND METHOD

Cells. Rat basophil leukaemia cells (RBL-2H3)) were from Dr. Metzger's laboratory (NIH, Bethesda, MD (11)). They were kindly provided by Dr. J. Kanellopoulos (Institut Pasteur, Paris). They were cultured in RPMI 1640 medium (Flow laboratories, GB) buffered with 20 mM HEPES, pH 7.2 and supplemented with 10 % fetal calf serum, 2 mM L-glutamin, 100 U/ml penicillin and 100 µg/ml streptomycin. They were detached from culture dishes with 2.5 % trypsin, then washed and maintained in RPMI 1640 medium.

Fluorescent labeling. Calcium monitoring was achieved by loading cells with 1 µM Fura2/AM (12) supplied by Calbiochem (La Jolla, CA) for 30 minutes at 37°C in a solution of 20 mM HEPES, 1 mM CaCl₂, 1 mM MgCl₂, 5 mM KCl, 10 mM glucose, 135 mM NaCl, 1 % bovine albumin, pH 7.4 (labeling buffer). They were then washed and used immediately in the same buffer.

Polymerized actin was revealed as described by Barak et al. (13) by fixing cells for 20 minutes with 3.7 % paraformaldehyde in phosphate buffer at room temperature, then labeling samples by another 20 minute incubation in phosphate buffer containing 10 U/ml 7-nitro-benz 2-oxa-1,3 diazoyl phalloidin (NBD-phalloidin, Molecular Probes, Eugene, OR) and 100µg/ml lysophosphatidylcholine (Sigma).

Microscopical observation. Cells (10⁶/ml) were deposited as 50 µl aliquots on glass coverslips (22x32 mm²) on the stage of an inverted IMT2 Olympus microscope equipped with a Lhesa 1036 video-amplified camera (Lhesa, Cergy Pontoise, France) with dual output. The sensitivity was 0.0015 lux. The first output was connected to a monochrome monitor (Zenith model ZVM 1230-EA) through a videotape recorder (Toshiba DV 90F) and a video timer/character generator (CG-C7S, JVC, Japan) allowing time reading with 0.1 second accuracy. The second output was connected to a PCVision+ digitizer (Imaging Technology, Woburn, MA) mounted on a PC20-III (IBM compatible) computer (Commodore business inc.). This performed real time digitization with 512x512 pixel resolution and 8-bit accuracy. The digitizer output was connected to a CDD-1402E multisync color monitor (Sony, Japan), allowing coded display with 256x256x256 colors. Images were stored on a floppy disk or a hard disk for delayed analysis. The linearity of light intensity determinations was checked as previously described (14). The microscope was modified by removing excitation filters from the blocks provided by the manufacturer and mounting combinations of excitation and neutral filters on a custom-made bar replacing the shutter used to switch off fluorescence illumination. It was thus possible to switch the excitation wavelength manually within about one second, allowing pH (15) and calcium monitoring by determination of the ratio R between fluorescence intensities obtained with two different illumination frequency domains. A laboratory-written software allowed superposition of two cell images with optimum correlation (in order to correct for a possible cell displacement during filter change), background subtraction and pixel-per-pixel intensity ratio calculation. Grynciewicz's formula (12) was used to calculate local calcium concentrations as follows :

$$(\text{Ca}^{2+})_i = K_d (R - R_{\min}) / (R_{\max} - R) L$$

where K_d is the affinity constant for association between fura-2 and calcium under intracellular ionic conditions (this was taken as 224 nM (12)). R_{\min} and R_{\max} are the ratios between fluorescence intensities at low (340 nm) and high (380 nm) excitation wavelength, these parameters were equal to 1.11 and 7.74 respectively under standard observation conditions (50 W mercury burner, 40X DPlanapo-UV objective). Parameter L is the ratio between fluorescence intensities measured at high wavelength excitation (380 nm) at high and low calcium concentration respectively and was equal to 0.21. Parameters R_{\min} , R_{\max} and L were obtained by studying cells incubated in buffer containing calcium and 1µM calcium ionophore ionomycin (Calbiochem), with or without an excess of EGTA to chelate free calcium.

Micropipette aspiration. We used the same methodology as was selected in a previous study made on macrophage deformability (16). Briefly, glass micropipettes were drawn out of capillary tubes (0.85 mm inner diameter ; Terumo, Tokyo, Japan) with a vertical pipette puller (David Kopf instruments, Tujunga, Ca) and enlarged to about 4 µm diameter by frontal shock against a smooth glass surface. They were then connected to a water-filled U tube manometer allowing pressure stabilization and reading with a few mm H₂O accuracy. Pipettes were held with a de Fonbrune type C pneumatic micromanipulator (Beaudouin, Paris) stuck on the microscope stage with a two-sided adhesive tape. The equilibrium pressure was determined by observation of the movements of free particles near the pipette mouth. Calcium monitoring was performed

increase, with subsequent calcium influx due to the high difference between extracellular and intracellular electrochemical potential of calcium ions. In order to test this possibility, we compared the calcium changes displayed by cells subjected to mechanical stress in calcium-containing and calcium-deprived media. As shown in table 1, similar calcium increases were observed under both experimental conditions. However, calcium rises were somewhat delayed in presence of an extracellular calcium chelator. Hence, some release of intracellular calcium stores must contribute the observed rise of cytosolic calcium.

Fig. 3. Kinetics of cytosolic calcium rise in mechanically stressed cells. Twenty-two individual cells were sucked into a micropipet at time zero, and the maximum local calcium concentration was measured at regular intervals. mean values are shown. vertical bar length is twice the SE.

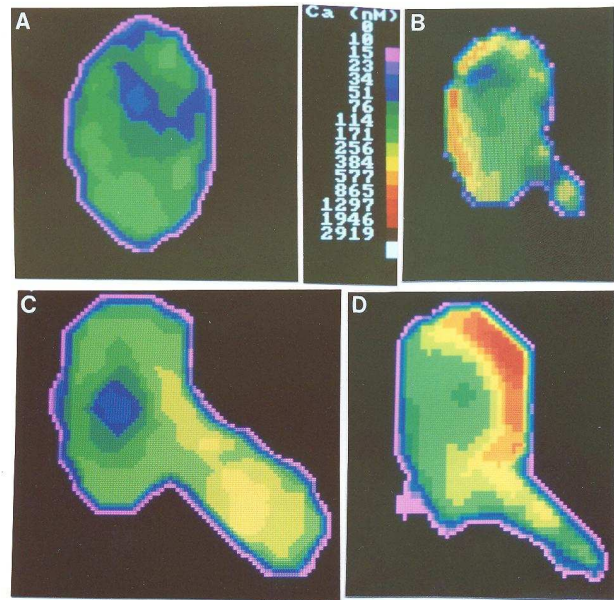

Fig. 4. Localization of calcium rise in mechanically stressed cells. the cytosolic calcium concentration was uniformly lower than 200 nM in resting cells (A). After aspiration, local calcium rises could be detected at distance from the pipet tip (B), in the cell protrusion (C), or near the pipet tip (D), with maximum values higher than 500 - 1000 nM.

Local calcium increase is often but not always located in regions of highest membrane tension. If cell calcium increases were initiated by local membrane stimulation, they might be expected to occur primarily at sites of maximum stress, i.e. near the pipette mouth or the protrusion tip (where the radius of curvature was highest). As shown on table 2, this occurred in nearly two thirds of observed cells, but some cells displayed definite calcium rise only at distance from the pipette tip. The most usual patterns of calcium distribution are exemplified in figure 4.

Table 1
Influence of extracellular calcium on cytosolic calcium rise in stressed cells

EGTA concentration	Maximum calcium level (nM) at time			Number of studied cells
	0 second	10 second	60 second	
0	81±16	257±48	200±30	26
5 mM	52±15	115±29	216±58	10

Cells were monitored for intracellular calcium distribution before and ten or sixty seconds after being sucked into micropipettes. The maximum local calcium concentration was then recorded. Experiments were conducted in calcium-containing and calcium-deprived medium. Mean values are shown ± standard error.

5 - Mechanical Cell Stimulation - Horoyan et al.

Sucking cells into micropipettes resulted in cytoskeletal reorganization. It was of interest to know whether the calcium rise we detected in stretched cells was associated to some structural or functional change. Since cytoskeletal elements are expected to play a role in cell deformation, we compared the distribution of polymerized actin in resting and deformed cells. Fourteen cells were stained with NBD-phalloidin after micropipette aspiration. All of them displayed a clearcut localized fluorescence accumulation (as exemplified in figure 1). Comparison between control and stressed cells (table 3) strongly suggested that *i*) no substantial actin polymerization was triggered by micropipette aspiration, since both groups of cells displayed similar labeling intensity, and *ii*) the apparent fluorescence concentration we reported was indeed a consequence of cell deformation, since the highest fluorescence intensity was substantially (50 %) and significantly ($P < 0.001$ according to Student's t test) higher in these cells than in controls (table 3).

Table 2
Localization of calcium rise in stressed cells

Time (second)	Number of cells with calcium rise			No calcium rise	Total cell number
	in protrusion	near pipette tip	far from pipette		
10	3	14	9	6	32
60	7	9	7	9	32

Thirty two cells were sucked into micropipettes and monitored for intracytoplasmic calcium distribution. Ten and sixty seconds after the onset of aspiration, most cells (26/32 and 23/32 respectively) displayed a local cytoplasmic rise as shown.

Table 3
Mechanical stress induces a local concentration of polymerized actin in mechanically stressed cells

Cell treatment	Mean cell fluorescence	Maximum local fluorescence	Number of studied cells
None (control)	51.4 ± 2.7	81.6 ± 5.6	11
Pipette aspiration	55.7 ± 2.6	128 ± 8.5 ($P < 0.001$)	14

Eleven control cells and fourteen cells that had been subjected for 4 minutes to micropipette aspiration were fixed and microfilaments were stained with NBD-phalloidin. Mean cell fluorescence and maximum pixel fluorescence were then recorded under the same conditions. Mean values are shown (using arbitrary units) ± Standard Error.

Table 4
Colocalization of cytosolic calcium rise and local microfilament accumulation in micropipette-aspirated cells.

		Localization of calcium rise			No calcium rise
		Protrusion	Near pipette tip	Elsewhere	
Localization of microfilament accumulation	Protrusion	1	0	0	1
	Near pipette tip	1	5	2	3
	Elsewhere	1	0	0	0

Fourteen individual RBL cells were subjected to micropipette aspiration for 4 minutes under calcium monitoring, then fixed and stained with NBD-phalloidin. All cells displayed local microfilament accumulation, and ten of them exhibited a local calcium rise. The localization of both events is shown.

Calcium rise and cytoskeletal accumulation do not always occur in the same cell region. An absolute correlation between the localization of calcium rise and cytoskeletal accumulation in individual cells would be strongly suggestive of the existence of a direct link between both events. However, as shown on table 4, there was no strict correlation between both phenomena. Hence, calcium changes might not be the only parameter involved in cytoskeletal reorganization.

6 - Mechanical Cell Stimulation - Horoyan et al.

Intracellular calcium changes do not substantially affect cell deformability. Despite the aforementioned conclusions, in view of previous evidence on the regulation of cell cytoskeleton (17, 18), it was reasonable to expect a direct relationship between intracellular calcium changes and alterations of cell deformability. This point was addressed by comparing the deformability of cells with high and low intracytoplasmic calcium. RBL cells were thus subjected to micropipette aspiration *i)* in control medium, *ii)* in presence of 10^{-6} M ionomycin and *iii)* in presence of 10^{-6} M ionomycin and 5 mM EGTA. The latter two procedures resulted in rapid rise and lowering of intracytoplasmic calcium level, as demonstrated with Fura 2 monitoring (not shown). However, as shown on table 5, both procedures induced only moderate although significant ($P<0.01$) decrease of cell deformability.

Table 5
Influence of calcium rise on the deformability of RBL cells

Extracellular medium	Length of the protrusion induced by a pressure of			Number of tested cells
	196 Pa	490 Pa	980 Pa	
Control	5.2±0.48	8.6±0.50	12.6±0.53	16
Ionomycin 1µM	4.4±0.61 (NS)	6.8±0.72 (P<0.05)	9.2±0.82 (P<0.01)	15
Ionomycin 1 µM + EGTA 5 mM	3.8±0.4 (P<0.05)	6.1±0.81 (P<0.05)	9.4±1.37 (NS)	21

Cells were sucked into micropipettes with increasing pressure for steps of 30 seconds each, and the length of the protrusion obtained after each step was measured. Mean values are shown ± Standard Error. The significance of the influence of ionomycin or ionomycin and EGTA was calculated with Student's t test and indicated in brackets. NS means : not significant at the 0.05 confidence level.

DISCUSSION

The goal of this work was to analyze cell responses to exogeneous stress. The first and quite unambiguous conclusion was that mechanical stress induced a complex biochemical response in rat basophilic leukaemia cells. Indeed, whereas the increase of membrane permeability induced by membrane stretching (8, 9, 10) might be viewed as some kind of transient leakage, our finding that stress induced a cytosolic calcium rise in a medium containing a chelator of this cation implies that intracellular calcium stores were mobilized, suggesting the occurrence of a cascade of intracellular events (19). A possible mechanism would be the formation of inositol trisphosphate as a consequence of phospholipase activation, with subsequent release of nonmitochondrial calcium (20). Note that it is not inconceivable that mechanical tension *per se* might activate membrane-embedded phospholipases, since a remarkable activation of these enzymes could be triggered by a reduction of about one dyne/cm of the surface pressure of a lipid layer (21), which is the same order of magnitude as the mechanical tension induced on the cylindrical wall of a protrusion of 2 cm radius by a sucking pressure of 1000 Pa.

Another point of importance concerning calcium measurements must be emphasized : Two-dimensional fluorescence images represent a convolution between three-dimensional fluorescence distributions and the point spread function of the optical system. Hence, what we called "local calcium concentration" was in fact the mean of calcium concentrations in an extended region of space. It is therefore possible that very localized and moderate calcium rises were missed in some cells. It must also be pointed out that the results we presented are in line with the previous finding by Maxfield and colleagues (22) that spreading of human neutrophils was immediately preceded by a calcium spike. Our data support the view that this might be related to a change of the plasma membrane tension, a possibility that was indeed considered by the authors (22).

A second conclusion is that mechanical stress induced a cytoskeletal response in RBL cells. Indeed, all micropipette-aspirated cells displayed a topological reorganization of polymerized actin as visualized with NBD-phalloidin. Since in thirteen cells out of fourteen a local actin concentration was found in the protrusion or near the pipette tip, an attractive hypothesis would be that there was a call for polymerized actin in the region of aspiration (i.e. near the pipette tip), resulting in a flow of blocks of gelled actin filaments that were sometimes stopped near the pipette mouth, resulting in local concentration increase. This

7 - Mechanical Cell Stimulation - Horoyan et al.

view is consistent with qualitative observations made on the deformation of human melanoma cells (23). The local calcium increases we described might result in separation of these blocks following local disruption of the gelled microfilament network, possibly due to gelsolin activation (18, 24). This view would be consistent with the lack of absolute correlation we reported between the localization of calcium spikes and cytoskeletal concentration.

Thirdly, our results strongly suggest that cells responded to exogeneous stress by active mechanical yield. Indeed, deeply perturbing cell cytoskeleton regulation by maintaining high or low value of cytoplasmic calcium resulted in moderate but significant decrease of cell deformability (table 5). It must be pointed out that increased cell stiffness was expected after calcium lowering (25, 26), not calcium increase (24), supporting the view that cytoskeletal regulation is not solely dependent on calcium ions. Further work is therefore required to correlate cell response to mechanical stress with other local events such as pH changes or protein phosphorylations. Clearly, only a detailed analysis of local cellular phenomena can allow a precise understanding of the mechanism of cell shape regulation.
