## Abstract Summary

HIV dynamics studies, based on differential equations, have significantly improved the knowledge on HIV infection. While first studies used simplified short-term dynamic models, recent works considered more complex long-term models combined with a global analysis of whole patients data based on nonlinear mixed models, increasing the accuracy of the HIV dynamic analysis. However statistical issues remain, given the complexity of the problem. We proposed to use the SAEM (Stochastic Approximation EM) algorithm, a powerful maximum likelihood estimation algorithm, to analyze simultaneously the HIV viral load decrease and the CD4 increase in patients using a long-term HIV dynamic system. We applied the proposed methodology to the prospective COPHAR2-ANRS 111 trial. Very satisfactory results were obtained with a model with latent CD4 cells defined with five differential equations. One parameter was fixed, the ten remaining parameters (eight with between patient variability) of this model were well estimated. We showed that the efficacy of nelfinavir was reduced compared to indinavir and lopinavir.

**Author Keywords** HIV dynamics ; Non linear mixed effects models ; SAEM algorithm ; Model selection

## Introduction

Understanding variability in response to antiretroviral treatment in HIV patients is an important challenge. HIV dynamic models describe the viral load decrease and the CD4 cells increase under treatment by modeling the interaction between several types of CD4 cells and virions (Perelson et al., 1996 ; Perelson and Nelson, 1997 ; Wu and Ding, 1999 ; Nowak and May, 2000 ; Rong and Perelson, 2009 ). They are defined as nonlinear differential systems and have generally no closed-form solutions. As available data are measurements of total number of the CD4 and the total number of virions, these differential systems are partially observed, complicating the parameter estimation. Nonlinear mixed effect models (NLMEMs) are appropriate to estimate model parameters and their inter-patient variability. The first modeling of viral load dynamic, using standard nonlinear regression or mixed models, considered a short time period and assumed non-infected CD4 cells to be constant (Perelson et al., 1996 ; Wu et al., 1998 ; Ding and Wu, 2001 ). Another simplified approach assumed inhibition of any new infection by initiated therapy. Under that unrealistic assumption, the system can be solved explicitly (Wu et al., 1998 ; Putter et al., 2002 ). Putter et al. (2002) proposed the first simultaneous estimation of the viral load and CD4 dynamics based on a differential system under this assumption, but had to focus only on the first two weeks of the dynamic after initiation of an anti-retroviral treatment. These two assumptions are unsatisfactory when studying long-term response to anti-retroviral treatment for which the use of complete models expressed as ordinary differential equations (ODEs) is mandatory.

Estimation of NLMEMs is complex because the likelihood has no closed form, even for simple models. Bayesian estimation methods based on Markov Chain Monte Carlo (MCMC) algorithms and informative priors have first been proposed for complex ODE HIV models and NLMEMs (Putter et al., 2002 ; Wu et al., 2005 ; Huang et al., 2006 ). The choice of informative prior distributions can be an issue. Furthermore, Bayesian algorithms can be very slow to converge, especially in this complex context. Wu et al. (2005) adjusted only viral load with a dynamic system describing the long-term HIV dynamics and considering drug potency, drug exposure/adherence and drug resistance during chronic treatment. However, the authors used a simplified model which does not consider separately the compartments of HIV-producing infected cells and the latent cells and does not decompose the virus compartment into infectious and non-infectious virions.

For maximum likelihood estimation in NLMEMs, likelihood approximations such as linearization (Pinheiro and Bates, 1995 ) or Laplace approximation (Wolfinger, 1993 ) have been proposed, leading to inconsistent estimates (Ding and Wu, 2001 ). Guedj et al. (2007a) proposed algorithms based on Gaussian quadrature but these algorithms are cumbersome and were not applied to problems with more than three random effects. Wu and Zhang (2002) proposed a semi-parametric approach. Other new algorithms are stochastic EM

algorithms as Monte Carlo EM (Wu, 2004 ). Among them, the Stochastic Approximation EM algorithm (SAEM) has convergence results ( Delyon et al., 1999 ; Kuhn and Lavielle, 2005 ), even for ODE models (Donnet and Samson, 2007 ). It is implemented in the MONOLIX software and has been mainly applied for the analysis of pharmacokinetics models (Lavielle and Mentré, 2007 ). Another complexity of viral load analysis is left censoring which occurs when viral load are below a limit of quantification (LOQ). The proportion of subjects with viral load below LOQ has increased with the development of highly active anti-retroviral treatment. Although it is known that when ignored, this censoring may induce biased parameter estimates (Samson et al., 2006 ; Thiébaud et al., 2006 ), several authors did not take into account this problem (Ding and Wu, 2001 ; Wu et al., 2005 ). Conversely, Hughes (1999) ; Fitzgerald et al. (2002) ; Thiebaut et al. (2005) ; Guedj et al. (2007a) proposed different approaches to handle accurately the censored viral load data. Samson et al. (2006) extended the SAEM algorithm to perform maximum likelihood estimation for left-censored data.

The first objective of this work was to estimate parameter of HIV dynamic models with the convergent SAEM algorithm. A second objective was to propose and apply statistical approaches for studying model selection in this context. We applied this approach to data obtained in patients of the clinical trial COPHAR2 - ANRS 111 (Duval et al., 2009 ) initiating an antiviral therapy with two nucleoside analogs (RTI) and one protease inhibitor (PI). We analyzed simultaneously the HIV viral load decrease and the CD4 increase based on a long-term HIV dynamic system. We considered three dynamic models and compare them with respect to their ability to represent HIV-infected patients after initiation of reverse transcriptase inverse (RTI) and protease inhibitor (PI) drugs therapy.

This article is organized as follows. Section 2 presents three mathematical models for long-term HIV dynamics. In Section 3, we discuss nonlinear mixed effects models and estimation with the SAEM algorithm, model selection, model identifiability and covariate testing. We, then, provide the results obtained in the COPHAR II-ANRS 134 clinical trial using MONOLIX in Section 4. Section 5 concludes this article with some discussion.

## Mathematical models for HIV dynamics after treatment initiation

Three nonlinear ordinary differential systems modeling the interaction of HIV virus with the immune system after initiation of antiviral treatment containing reverse transcriptase inhibitor (RTI) and protease inhibitor (PI) are presented.

### The basic dynamic model

Let  $T_{NI}$ ,  $T_I$  and  $V_I$  denote the concentration of target noninfected CD4 cells, productively infected CD4 cells and infectious viruses, respectively. Following Perelson and Nelson (1997) ; Perelson (2002) , it is assumed that CD4 cells are generated through the hematopoietic differentiation process at a constant rate  $\lambda$ . The target cells are infected by the virus at a rate  $\gamma$  per susceptible cell and virion. Noninfected CD4 cells die at a rate  $\mu_{NI}$  whereas infected ones at a rate  $\mu_I$ . Infected CD4 cells produce virus at a rate  $p$  per infected cell. The virus are cleared at a rate  $\mu_V$ . Two additional parameters  $\eta_{RTI}$  and  $\eta_{PI}$  are introduced to model the effect of antiviral therapy containing RTI and PI. RTI prevents susceptible cells from becoming infected through inhibition of the transcription of the viral RNA into double-stranded DNA.  $\eta_{RTI}$  denotes the proportion of susceptible cells prevented to be infected and is valued between 0 and 1. A value of  $\eta_{RTI} = 1$  corresponds to a completely effective drug. PI leads to the production of noninfectious viruses  $V_{NI}$  which is modeled trough an additional equation.  $V_{NI}$  are produced at a rate  $\eta_{PI} p$  where  $\eta_{PI}$  is a proportion between 0 and 1 and where  $\eta_{PI} = 1$  corresponds to a completely effective drug. It is assumed that infectious and non infectious viruses die at the same rate  $\mu_V$ . Under combined PI and RTI action, the system is written:

$$\begin{aligned}\frac{dT_{NI}}{dt} &= \lambda - (1 - \eta_{RTI})\gamma T_{NI}V_I - \mu_{NI}T_{NI} \\ \frac{dT_I}{dt} &= (1 - \eta_{RTI})\gamma T_{NI}V_I - \mu_I T_I \\ \frac{dV_I}{dt} &= (1 - \eta_{PI})pT_I - \mu_V V_I \\ \frac{dV_{NI}}{dt} &= \eta_{PI} pT_I - \mu_V V_{NI}\end{aligned}$$

It is assumed that before the treatment initiation, the system has reached an equilibrium state (the steady state values are given in the Web Appendix A ). The measured viral load is the total viral load  $V = V_I + V_{NI}$  and the measured CD4 cell count is the total  $T = T_{NI} + T_I$ . This basic model is called

. Its parameters and their definitions are summarized in Table 1 .

### The quiescent dynamic model

De Boer and Perelson (1998) ; Guedj et al. (2007a) proposed a more elaborated model which distinguishes quiescent CD4 cells,  $T_Q$ , target (activated) noninfected cells,  $T_{NI}$ , and infected T cells,  $T_I$ . Only activated CD4 cells become infected with HIV, and quiescent cells are assumed to be resistant to infection. Quiescent CD4 cells  $T_Q$  are generated through the hematopoietic differentiation process at a constant rate  $\lambda$ . As the CD4 cell compartment is largely maintained by self-renewal, the dynamic model allows the quiescent CD4 cells to become activated at a low constant rate  $\alpha_Q$ . Quiescent CD4 cells are assumed to die at a rate  $\mu_Q$ , and to appear by the deactivation of activated noninfected CD4 cells at a rate  $\rho$ . The system of differential equations describing this model after treatment initiation is written as:

$$\begin{aligned}\frac{dT_Q}{dt} &= \lambda + \rho T_{NI} - \alpha_Q T_Q - \mu_Q T_Q \\ \frac{dT_{NI}}{dt} &= \alpha_Q T_Q - (1 - \eta_{RTI}) \gamma T_{NI} V_I - \rho T_{NI} - \mu_{NI} T_{NI} \\ \frac{dT_I}{dt} &= (1 - \eta_{RTI}) \gamma T_{NI} V_I - \mu_I T_I \\ \frac{dV_I}{dt} &= (1 - \eta_{PI}) p T_I - \mu_V V_I \\ \frac{dV_{NI}}{dt} &= \eta_{PI} p T_I - \mu_V V_{NI}.\end{aligned}$$

As proposed by Perelson et al. (1996), it is assumed that newly produced viruses are fully infectious before the introduction of a PI treatment and that before the treatment initiation, the system has reached an equilibrium state (see the Web Appendix A). The measured viral load is the total viral load  $V = V_I + V_{NI}$  and the measured CD4 cell count is the total  $T = T_Q + T_{NI} + T_I$ . This quiescent model is called . Its parameters and their definitions are summarized in Table 1 .

### The latent dynamic model

Funk et al. 2001 considered that not all CD4 cells actively produce virus upon successful infection. Infected cell pool is split into actively and latently infected cells. Uninfected CD4 cells are infected by the virus, as previously, at a rate  $(1 - \eta_{RTI}) \gamma V_I$ . But only a proportion  $\pi$  of this infected cells are activated CD4 cells,  $T_A$ , and a proportion  $(1 - \pi)$  are latently infected CD4 cells,  $T_L$ . Latently infected CD4 cells die at a rate  $\mu_L$  and become activated at a rate  $\alpha_L$ . Actively infected cells  $T_A$  die at a rate  $\mu_A$  and only these cells produce virus particles. The differential system describing this model after treatment initiation is written:

$$\begin{aligned}\frac{dT_{NI}}{dt} &= \lambda - (1 - \eta_{RTI}) \gamma T_{NI} V_I - \mu_{NI} T_{NI} \\ \frac{dT_L}{dt} &= (1 - \pi)(1 - \eta_{RTI}) \gamma T_{NI} V_I - \alpha_L T_L - \mu_L T_L \\ \frac{dT_A}{dt} &= \pi(1 - \eta_{RTI}) \gamma T_{NI} V_I + \alpha_L T_L - \mu_A T_A \\ \frac{dV_I}{dt} &= (1 - \eta_{PI}) p T_A - \mu_V V_I \\ \frac{dV_{NI}}{dt} &= \eta_{PI} p T_A - \mu_V V_{NI}.\end{aligned}$$

As previously, it is assumed that before treatment initiation, the system has reached an equilibrium state (see the Web Appendix A). The measured viral load is the total viral load  $V = V_I + V_{NI}$  and the measured CD4 cell count is the total  $T = T_{NI} + T_L + T_A$ . This latent model is called

. Its parameters and their definitions are summarized in Table 1 .

## Statistical Methods

### The nonlinear mixed effects model

Let  $N$  be the number of patients. For patient  $i$ , we measure  $n_i$  viral loads at times  $(t_{ij})$ ,  $j = 1, \dots, n_i$  and  $m_i$  CD4 cells at times  $(\tau_{ij})$ ,  $j = 1, \dots, m_i$ . Let us define  $v_i = (v_{i1}, \dots, v_{in_i})$  where  $v_{ij}$  is the observed  $\log_{10}$  HIV viral load (cp/mL) for individual  $i$  at time  $t_{ij}$ ,  $i = 1, \dots, N$ ,  $j =$

$1, \dots, n_i$ , and  $z_i = (z_{i1}, \dots, z_{im_i})$  where  $z_{ij}$  is the CD4 cell count (cells/mm<sup>3</sup>) for individual  $i$  at time  $\tau_{ij}$ ,  $i = 1, \dots, N$ ,  $j = 1, \dots, m_i$ . The observed log<sub>10</sub> viral load and the CD4 cell count of all patients are analyzed simultaneously using a nonlinear mixed effects model, where  $V$  and  $T$  are the total number of virus (cp/mm<sup>3</sup>) and CD4 cells (cells/mm<sup>3</sup>):

$$\begin{aligned} v_{ij} &= \log_{10}(1000 V(\tau_{ij}; \psi_i)) + e_{V,ij}, & e_{V,i} &\sim N(0, \sigma_V^2 I_{n_i}) \\ z_{ij} &= T(\tau_{ij}; \psi_i) + T(\tau_{ij}; \psi_i) e_{T,ij}, & e_{T,i} &\sim N(0, \sigma_T^2 I_{m_i}) \\ \psi_i &= h(\varphi_i), & \varphi_i &\sim N(\mu, \Omega). \end{aligned}$$

Note that  $V$  is expressed in cp/mm<sup>3</sup> and the observed  $v$  in log<sub>10</sub>-cp/mL, hence the 1000 in equation (5). Here  $(e_{V,ij})$  and  $(e_{T,ij})$  represent the residual errors. We assume a constant error model for the log viral load and a proportional error model for the CD4 concentration. Several error models will be tested for the CD4 count. Different parametric models for  $V$  and  $T$  were previously proposed. These models are functions of individual parameters  $\psi_i$ , which are assumed to be independent of the residual errors  $(e_{V,i}, e_{T,i})$ . The parameters  $\psi_i$  are assumed to be some transformation  $h(\varphi_i)$  of a Gaussian random vector  $\varphi_i$  with mean  $\mu$  (the vector of fixed effects) and variance-covariance  $\Omega$  (the covariance matrix of the random effects). As inhibition parameters  $\eta_{RTI}$  and  $\eta_{PI}$  take their values in  $[0, 1]$ , they are defined as the logistic transformation of a Gaussian random variable. For model

,  $\pi$  is defined as the logistic transformation of a Gaussian random variable. Others parameters are non-negative parameters and defined as the exponential transformation of Gaussian random variables.

The observation model is complicated by the detection limit of assays. When viral load data  $v_{ij}$  is below the limit of quantification LOQ, the exact value  $v_{ij}$  is unknown and the only available information is  $v_{ij} \leq \text{LOQ}$ . These data are classically named left-censored data. Let denote  $I_{\text{obs}} = \{(i, j) | v_{ij} \geq \text{LOQ}\}$  and  $I_{\text{cens}} = \{(i, j) | v_{ij} \leq \text{LOQ}\}$  the index sets of respectively the uncensored and censored observations. Finally, we observe

$$v_{ij}^{\text{obs}} = \begin{cases} v_{ij} & \text{if } (i, j) \in I_{\text{obs}} \\ \text{LOQ} & \text{if } (i, j) \in I_{\text{cens}} \end{cases}$$

### Parameters estimation

Let  $\theta = (\mu, \Omega, \sigma_T^2, \sigma_V^2)$  be the set of unknown population parameters. Maximum likelihood estimation of  $\theta$  is based on the likelihood function of the observations  $(v^{\text{obs}}, z)$ :

$$l(v^{\text{obs}}, z, \theta) = \prod_{i=1}^N \int \int p(v_i^{\text{obs}}, v_i^{\text{cens}}, z_i, \varphi_i; \theta) d\varphi_i dv_i^{\text{cens}}$$

where  $p(v_i^{\text{obs}}, v_i^{\text{cens}}, z_i, \varphi_i; \theta)$  is the likelihood of the complete data  $(v_i^{\text{obs}}, v_i^{\text{cens}}, z_i, \varphi_i)$  of the  $i$ -th subject. As the random effects  $\varphi_i$  and the censored observations  $v_i^{\text{cens}}$  are unobservable and as the regression functions are nonlinear, the foregoing integral has no closed form. Therefore the maximum likelihood estimate is not available in a closed form.

We propose to use the Stochastic Approximation Estimation Maximisation (SAEM) algorithm, a stochastic version developed by Delyon et al. (1999) of the Expectation-Maximization algorithm introduced by Dempster et al. (1977). This algorithm computes the E-step of the EM algorithm through a stochastic approximation scheme. It requires a simulation of one realization of the non observed data in the posterior distribution at each iteration, avoiding the computational difficulty of independent samples simulation of the Monte-Carlo EM and shortening the time consumption. SAEM algorithm is a stochastic algorithm, for which almost-sure convergence toward the maximum likelihood estimation is ensured under general conditions (Delyon et al., 1999). As the simulation of the non observed data in the posterior distribution is not direct for NLMEMs, Kuhn and Lavielle (2005) proposed to combine the SAEM algorithm with a MCMC method to realize this simulation step. Donnet and Samson (2007) proposed a version of the SAEM algorithm adapted to mixed models defined by differential equations. The SAEM algorithm also enables to take into account the left-censored viral load data accurately with convergent estimator (Samson et al., 2006). The combination of the two extensions of SAEM for differential equations and for left-censored data handling is used in the following analyzes.

### Model selection

Model selection aims at identifying a model that best fits the available data with the smallest possible dimension. The two most popular model selection criteria are the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC). Following the simulation results of Bertrand et al. (2008), the best model is defined here as the model with the lowest BIC. Let

be the number of parameters in the model

,

the likelihood function of the observations  $(v^{\text{obs}}, z)$  and

the maximum likelihood estimate of  $\theta$  in model

. The BIC penalizes the minimized deviance by  $\log(N)$  times the number of free parameters.

$$BIC(\mathcal{M}) = -2 \log l_{\mathcal{M}}(\mathbf{v}^{\text{obs}}, \mathbf{z}; \hat{\boldsymbol{\theta}}_{\mathcal{M}}) + \log(N) P_{\mathcal{M}}.$$

Using BIC requires to compute the log-likelihood of model

. Following (5), for any model

, the likelihood  $l$  of the observations  $(\mathbf{v}^{\text{obs}}, \mathbf{z})$  can be decomposed as follows (we omit the subscript to simplify the notation):

$$l(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta}) = \int p(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\varphi}; \boldsymbol{\theta}) d\boldsymbol{\varphi} = \int h(\mathbf{v}^{\text{obs}}, \mathbf{z} | \boldsymbol{\varphi}, \boldsymbol{\theta}) \frac{\pi(\boldsymbol{\varphi}; \boldsymbol{\theta})}{\tilde{\pi}(\boldsymbol{\varphi}; \boldsymbol{\theta})} \tilde{\pi}(\boldsymbol{\varphi}; \boldsymbol{\theta}) d\boldsymbol{\varphi}$$

where  $\pi$  is the probability distribution density of  $\boldsymbol{\varphi}$  and  $\tilde{\pi}$  any absolutely continuous distribution with respect to  $\pi$ . Then,  $l(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$  can be approximated via an Importance Sampling integration method:

- draw  $\boldsymbol{\varphi}^{(1)}, \boldsymbol{\varphi}^{(2)}, \dots, \boldsymbol{\varphi}^{(K)}$  with the distribution  $\tilde{\pi}(\cdot; \boldsymbol{\theta})$ ,

- let  $\hat{l}_K(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta}) = \frac{1}{K} \sum_{i=1}^K h(\mathbf{v}^{\text{obs}}, \mathbf{z} | \boldsymbol{\varphi}^{(i)}, \boldsymbol{\theta}) \frac{\pi(\boldsymbol{\varphi}^{(i)}; \boldsymbol{\theta})}{\tilde{\pi}(\boldsymbol{\varphi}^{(i)}; \boldsymbol{\theta})}$

$\hat{l}_K(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$  is a consistent estimator of the observed likelihood:

$$E(\hat{l}_K(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})) = l(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta}) \text{ and } \text{Var}(\hat{l}_K(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})) =$$

$(K^{-1})$ . Furthermore, if  $\tilde{\pi}$  is the conditional distribution  $p(\boldsymbol{\varphi} | \mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$ , the variance of the estimator is null and  $\hat{l}_K(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta}) = l(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$  for any value of  $K$ . That means that an accurate estimation of  $l(\mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$  can be obtained with a small value of  $K$  if the sampling distribution is close to the conditional distribution  $p(\boldsymbol{\varphi} | \mathbf{v}^{\text{obs}}, \mathbf{z}; \boldsymbol{\theta})$ .

We recommend the following procedure: for  $i = 1, 2, \dots, N$ , one estimates empirically the conditional mean  $E(\boldsymbol{\varphi}_i | \mathbf{v}_i^{\text{obs}}, \mathbf{z}_i; \hat{\boldsymbol{\theta}})$  and the conditional variance-covariance matrix  $\text{Var}(\boldsymbol{\varphi}_i | \mathbf{v}_i^{\text{obs}}, \mathbf{z}_i; \hat{\boldsymbol{\theta}})$  of  $\boldsymbol{\varphi}_i$  as described above. Then, the  $\boldsymbol{\varphi}_i^{(k)}$  are drawn with the sampling distribution  $\tilde{\pi}$  as follows:

$$\boldsymbol{\varphi}_i^{(k)} = E(\boldsymbol{\varphi}_i | \mathbf{v}_i^{\text{obs}}, \mathbf{z}_i; \hat{\boldsymbol{\theta}}) + \text{Var}(\boldsymbol{\varphi}_i | \mathbf{v}_i^{\text{obs}}, \mathbf{z}_i; \hat{\boldsymbol{\theta}})^{\frac{1}{2}} \times \mathbf{T}_i^{(k)}$$

where  $(\mathbf{T}_i^{(k)})$  is a sequence of i.i.d. random vectors and where the components of  $\mathbf{T}_i^{(k)}$  are independent variables distributed with a  $t$ -distribution with  $\nu$  degrees of freedom. The numerical results presented here were obtained with  $\nu = 5$  d.f.

Note that recently, several authors proposed conditional Information Criteria for linear mixed models, see Liang et al. (2008) for example. The use of such criteria seems promising but extension to non linear mixed model is not straightforward.

### Model identifiability

If the ODE model is not identifiable, any estimation method may produce unreliable and misleading results. Then, identifiability of the model parameters has to be checked before applying the HIV dynamic model to the data. Usually, many of the model components may not be measurable and several parameters may not be identifiable. We need a trade-off between model complexity and parameter identifiability based on clinical data. If a model has too many components, it may be difficult to analyze. If a model is too simple, some important clinical factors cannot be incorporated, although the viral dynamic parameter can be identified and estimated. Various works on system identification of nonlinear HIV models can be found for example in Perelson and Nelson (1997); Xia and Moog (2003); Jeffrey and Xia (2005); Guedj et al. (2007b); Wu et al. (2008). Xia and Moog (2003) proposed a HIV dynamic model defined with a system of 4 ODEs and checked the algebraical identifiability. Assuming that the non infected cells are observed, their system allows to derive some sufficient conditions which ensure the algebraic identifiability of the model. Unfortunately, the different models that we consider do not allow to separate the problem into two independent problems as proposed by Xia and Moog (2003) or by Wu et al. (2008) and the identifiability of the complete set of the parameters must be discussed on the whole. This problem has no closed form algebraic conditions. As an alternative, we propose to examine the algebraic identifiability problem by performing some sensitivity analysis.

Nevertheless, even if algebraic identifiability is useful, it is not completely appropriate for a population approach where the distribution of the individual parameters is also part of the (statistical) model. In other word, if a parameter is not algebraically identifiable, it can be statistically identifiable (an example is given in the Web Appendix A) and the reverse is also true: some parameters can be difficult to estimate with a very poor design, even if the model is algebraically identifiable. Then, practical identifiability should also be considered (see Guedj et al. (2007b) for example). As a practical diagnostic tool, we propose to use the Fisher Information Matrix for detecting some over-parametrization in the model. From our experience, very large standard errors (or NaN) indicate some issues in the

parametrization, but the reverse is not necessarily true ... We recommend to perform several runs with slightly different initial guesses. Then, convergence to different solutions can indicate a lack of identifiability, rather than the presence of several isolated local maxima of the likelihood.

### Covariate testing

Another statistical issue in NLMEMs is the utilization of covariates to explain part of inter-individual parameter variability. Comparing models with and without covariates can be performed through model selection with the BIC criterion. For nested models, the likelihood ratio test can be applied by computing the log-likelihoods of the nested models. The Wald test can be used based on the covariates estimated effects and their standard errors.

### The MONOLIX software

Monolix is a free software (<http://software.monolix.org>), which implements a wide variety of stochastic algorithms such as SAEM, Importance Sampling, MCMC, and Simulated Annealing, all dedicated to the analysis of NLMEMs. The objectives are: a) parameter estimation by computing the maximum likelihood estimator of the parameters without any approximation of the model and standard error for the maximum likelihood estimator; b) model selection by comparing several models using some information criteria (AIC, BIC), testing hypotheses using the Likelihood Ratio Test, testing parameters using the Wald Test and c) Goodness of fit. Monolix version 2.4 was used in this work. We used the code BiM (release 2.0, April 2005) which implements a variable stepsize method for stiff initial value problems for ODEs.

## Application to the COPHAR II - ANRS 134 trial

### Material and Methods

In the COPHAR II- ANRS 134 trial, an open prospective non-randomized interventional study, 115 HIV-infected patients adults started an antiviral therapy with at least 2 RTIs and one of three different PIs. 48 patients were treated with indinavir (and ritonavir as a booster)(I), 38 with lopinavir (and ritonavir as a booster) (L) and 35 with nelfinavir (N). Patients were followed one year after treatment initiation. Viral load and CD4 cell count were measured at screening, at inclusion and at weeks 2(or 4), 8, 16, 24, 36 and 48. Plasma HIV-1-RNA were measured by Roche monitored with a limit of quantification of 50 copies/ml. The results of this trial are reported in Duval et al. (2009). The proportion of virological failure was higher in the nelfinavir group and similar for indinavir and lopinavir, although lopinavir is supposed to be a more potent PI now widely used. Observed viral load and CD4 cell count are displayed in Figure 1 which clearly shows a large inter-subject variability.

,

and

were compared using the BIC criterion. The identifiability of the selected model was studied, the effect of the PI group is tested by adding a covariate on  $\eta_{PI}$ :

$$\text{logit}(\eta_{PI, i}) = \mu + \beta_{TRT_i} + b_i$$

where  $TRT_i$  is the PI administrated to patient  $i$  (L, I or N). The reference group is the lopinavir group ( $\beta_L = 0$ ). BIC and Wald test were used to study the differences in the 3 PI groups: no PI effect (LIN), only two groups: L vs. IN (L-IN) or LI vs N (LI-N), three groups L-I-N.

### Results

We compared the three dynamic models. For each model, the complete set of fixed effects (Table 1) were estimated. Furthermore, variability on all the parameters was assumed without any correlation between the random effects. The population parameters were estimated with the SAEM algorithm and the log-likelihoods were estimated by Monte Carlo Importance Sampling. The BIC computed for the three models. The latent model

was selected as the best model among the three candidate models: BIC(

)=8758, BIC(

)=9077, BIC(

)=9134. Furthermore, the fits for both the viral load and the CD4 counts were better with model

( $\sigma_v = 0.46$  and  $\sigma_T = 0.25$ ) than with model

( $\sigma_v = 0.62$  and  $\sigma_T = 0.27$ ) or model

( $\sigma_v = 0.67$  and  $\sigma_T = 0.27$ ).

We then studied the identifiability of

. First we studied the mathematical identifiability by performing a sensitivity analysis on a single simulated individual that showed that individual fitting does not allow to estimate simultaneously three sets of parameters:  $(p, \mu_v)$ ,  $(\gamma, \pi, p, \mu_A)$  and  $(\eta_{PI}, \eta_{RTI})$  (see Web Appendix B for more details).

The sensitivity analysis showed that only the ratio  $p/\mu_v$  can be estimated. The problem of estimating both  $p$  and  $\mu_v$  was also found in the Fisher Information Matrix obtained after running the SAEM algorithm with very high estimated standard errors (236% and 240% respectively). Therefore, we assumed that  $\mu_v$  did not vary and was fixed to the value 30/day (Ramratnam et al., 1999 ; Guedj et al., 2007a ). Fixing  $\mu_v$  to any other value around 30/day didn't change the estimation of the other parameters, except  $p$ . We also found that both  $\gamma$  and  $\mu_L$  could be correctly estimated (their s.e. were estimated to 43% and 11%) but not their inter-patient variability. We therefore decided to estimate these two parameters, but considering that they do not vary in the population. For the third set, the sensitivity analysis clearly showed that, using the data from only one patient, only the product  $(1 - \eta_{PI})(1 - \eta_{RTI})$  can be estimated. Then, we tried to fix  $\eta_{PI}$  or  $\eta_{RTI}$  but the results were clearly deteriorated. That means that the probability distribution of  $(1 - \eta_{PI})(1 - \eta_{RTI})$  cannot be described assuming that only one of these two parameters is a random variable. Thus, we assumed that both  $\eta_{PI}$  and  $\eta_{RTI}$  vary in the population because both are statistically identifiable (see discussion on that in Web supplement ).

Table 3 reports BIC and estimated  $\beta$ 's for the different merging of the PI group (BIC and LL are different from Table 2 because parameter  $\mu_v$  was fixed in Table 3 ). Adding a covariate treatment to explain the variability of  $\eta_{PI}$  did not modify the identifiability of the model. Different starting values always gave similar results for the  $\beta$ 's. The smallest BIC was for LI-N implying a different effect of nelfinavir versus lopinavir and indinavir that were grouped. The estimated parameters of that model are reported in Table 4. The efficacy of PI  $\eta_{PI}$  was 0.99 for lopinavir-indinavir and 0.75 for nelfinavir, i.e. nelfinavir efficacy for blocking infectious viruses was 25% less important than for lopinavir and indinavir, which are boosted PI. The LRT for the nelfinavir effect was very significant ( $p = 10^{-12}$  for comparison of models LIN and LI-N), no significant improvement was found when separating L and I (comparison of models LI-N vs L-I-N:  $p = 0.32$  ). The Wald tests also agreed that only  $\beta_N$  was significantly different from zero.

This model provided good fits of both viral load and CD4 cells as can be seen on the visual predictive check (Figure 2 ) and on some individual fits for patients in each treatment group (Figure 3 ).

We also tested several error models for the CD4 count. Thiebaut et al. (2005) assumed a constant error model for the CD4 count at the power 0.25 ( $z^{1/4} = T^{1/4} + \epsilon$  ). For this error model as well as for the constant error model, the log-likelihood was lower ( $-2 \times LL = 8680$ ) and the proportional error model was preferred ( $-2 \times LL = 8635$ ) for the final model.

Convergence of SAEM takes about 20mn on a Dual Core laptop. The total time for estimating the population parameters with SAEM, the Fisher Information Matrix, the individual parameters and the log-likelihood is about 1 hour.

## Discussion

This article proposed the SAEM algorithm to estimate parameters of nonlinear mixed model based on partially observed complex HIV differential systems. The estimation of the parameters of such a mixed model is a difficult statistical and computational challenge. The HIV differential systems defining these mixed models are non linear, consequently without any analytical solution. Furthermore, the ODE system is generally stiff , the classic ODE solver such as Runge-Kutta not being adapted to solve numerically the system. We used the code BiM (release 2.0, April 2005) which implements a variable order-variable stepsize method for (stiff) initial value problems for ODEs. The analysis of such data is also complicated by the left-censoring of the viral load data due to the lower limit of experimental devices detection, and it is well known that omitting to correctly handle this censored data provides biased estimates of dynamic parameters. The SAEM algorithm has theoretical convergence properties and is computationally efficient on these dynamic models.

In this article, we applied it to a clinical trial in HIV infection, using all the data (both viral load and CD4 measurements) obtained during 48 weeks of follow-up in naive patients starting a treatment while most studies of HIV dynamics model studied only viral load data during a shorter period (2–6 weeks) after the initiation of anti-retroviral treatment.

We compared several HIV dynamic models and showed that the latent model was the best one using the BIC criterion. We also studied the practical identifiability of this model. Using likelihood ratio test to compare the efficacy of the three studied PI, we found a significant difference in the efficacy of nelfinavir compared to lopinavir or indinavir. This is in agreement with the results of the trial ( Duval et al; 2009 ) in which virological failure was found in 33% of patients treated with nelfinavir and only in 5% of patients treated by indinavir or lopinavir.

The HIV dynamic model used in this study has some limitations. First, it does not take into account the fact that HIV undergoes rapid mutation in the presence of anti-retroviral therapy. Of course, considering such phenomenon in the model may introduce many more parameters. We attempted to keep the model itself as simple as possible and the goodness of fit were satisfactory. Second, we considered a

constant treatment effect, however, the effect of antiviral treatment may change over time, due to pharmacokinetics intra-patient variability, fluctuating patient adherence, emergence of drug resistance mutations and/or other factors. Huang et al. (2006) proposed viral dynamic models to evaluate antiviral response as a function of time-varying concentrations of drug in plasma. A more elaborate model would thus promisingly include this additional extension. Nevertheless, these limitations did not offset the major findings from our modeling approach, although further improvement may be brought. In conclusion, the SAEM algorithm is an useful tool for model development and parameter estimation in this context of HIV dynamics.

## Acknowledgements:

The authors would like to thank the scientific committee of COPHAR II-ANRS111 trial for giving us access to the data, especially the principal investigators Pr Dominique Salmon-Céron from Infectious Diseases Unit at Cochin Hospital, Paris and Dr Xavier Duval from Center for Clinical Investigation, Bichat Hospital, Paris, France. We thank Xavière Panhard (INSERM UMR738) for her help in managing the data of the trial and discussion on the choice of models.
