Abstract

Semi-invasive *foramen ovale* (*Fov*) electrodes were used to record electrical activity in the vicinity of the inferior mesial temporal region of epileptic patients, in addition to standard scalp EEG. Third order cumulant analysis was used to measure the phase-coupled frequencies corresponding to non-linear coupling of spectral frequency components, somewhat analogous to frequencies of resonance. On the basis of the distribution of these frequencies, an index of resonance (*IR*) is defined as the ratio between the number of peaks in the gamma-band (40 – 55 Hz) vs. the number of peaks in the beta-band (15 – 30 Hz). The epileptogenic focus was located in the hemisphere with lower resonant frequencies because these frequencies were characteristic of a spread of the seizure over a broader area. In the case of *Fov* electrodes *IR* could differentiate a group of patients affected by a tumor compared to patients with mesial temporal sclerosis. The novel index *IR* appears as an interesting parameter to evaluate the level of interareal functional connectivity in *Fov* recordings in epileptic patients, but its usage is likely to be extended in electrophysiological studies.

Key words: Mesiotemporal lobe epilepsy, epileptic focus, cortico-cortical resonances, bispectrum, bicoherence

1. Introduction

Patients with medically refractory mesiotemporal epilepsy are characterized by an actively discharging epileptiform region that induces paroxysmal behavior in a homologous site of the contralateral hemisphere (Williamson et al., 1993; Steinhoff et al., 1995). Entrainment of both temporal and frequency domain characteristics of temporal lobe activity may depend on both local connections and external inputs, mainly cortico-cortical and thalamic (Canolty et al., 2006; Jensen and Colgin, 2007). The exact localization and spreading pattern of the seizure can be assessed with electrophysiological recordings only from subdural and depth electrodes (King and Spencer, 1995) and is otherwise determined by neuroimaging techniques (Velasco et al., 2002; Joo. et al., 2004). However, the invasiveness and the costs of these methods may not be made available or tolerated by several patients.

Non-invasive electroencephalographic (EEG) recordings with scalp electrodes are routinely performed on epileptic patients but these data may be distorted by skull defects and underlying lesions or deformities of the brain (Scherg et al., 1999). Semi-invasive (*foramen ovale*, *Fov*) electrodes allow to record electrical activity in the vicinity of the inferior mesial temporal region with less artifacts (Wieser et al., 1985; Carter et al., 1998) and become more often used in addition to the standard international EEG 10/20 montage positions. Then, these recordings may offer the advantage of exploring mesiotemporal lobe activity with higher-order frequency domain analyses—bispectral analysis—that allow to determine the nonlinear com-

ponents of the interactions in the frequency domain (Brillinger, 1965; Lii and Helland, 1981; Schanze and Eckhorn, 1997).

Bicoherence is a normalization method which compares the actual bispectrum with a zero phase bispectrum, i.e. a bispectrum with the highest degree of phase coupling (Nikias and Raghuvver, 1987). It shows the degree of phase coupling between frequency components of one or more signals. In brain electric activity, such non-linearities would occur when two frequency components are in harmonic resonance or if two brain electric waves interact and generate a new energy component at a frequency, called Quadratic Phase coupling, which is the sum of the frequencies of its source components. Bispectral analysis was used for the study of non-linear interactions in several animal studies (Villa et al., 1999, 2000). In human studies, bispectral analysis of EEG (Ning and Bronzino, 1993; Sigl and Chamoun, 1994; Johansen and Sebel, 2000) became routinely applied for studying the levels of arousals and anesthesia with controversial outcome (Hagihira et al., 2002; Miller et al., 2004; Schulz et al., 2007) and to cognitive studies of areal interactions (Freeman et al., 2003; Jensen and Colgin, 2007).

Dynamic brain oscillations have extensively been studied in epileptic patients and revealed several changes in the power spectra of EEG signal before and after the epileptic seizures (Le Van Quyen and Bragin, 2007). Recent evidence of spectral instabilities during the pre-ictal intervals (Aksenova et al., 2007) suggest that scalp and *Fov* recordings might reveal more information about the activity of neural circuits after careful analysis of bispectra. In the current study we define a novel index, called index of resonance, based on third order spectral (bispectral) analysis of EEG recordings. We report the application of this method to EEG data (scalp and *Fov* record-

Email addresses: Alessandro.Villa@ujf-grenoble.fr (Alessandro E.P. Villa)

ings) recorded in patients characterized by medically refractory complex partial seizures. In addition to its clinical application, such index might be used in other studies to describe dynamic changes of neural interactions.

2. Methods

2.1. Patients data

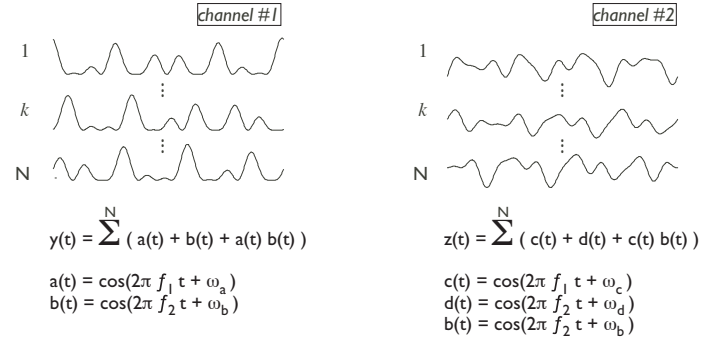

We analyzed the data of ten patients, 9 men and 1 woman (mean age, 26.6 years; range, 13-39 years), all with therapy refractory mesiotemporal epilepsy. Four patients were affected by mesotemporal sclerosis and underwent hippocampal amygdalotomy. Five were affected by different types of tumors and underwent resection of the tumor. One patient was characterized by a traumatic lesion of the temporal lobe and underwent a 2/3 anterior temporal lobe resection. All patients were seizure-free during at least one year post-operation. The patients were consecutively examined in the local program for presurgical evaluation, which has been approved by the ethical committee of the University of Bern. Informed consent about using the routine diagnostic data for research purposes was given by all patients prior to entering the presurgical evaluation program.

2.2. EEG data acquisition

For scalp EEGs the standard 10/20 montage positions were used with referential montages to two preauricular electrodes. For analyzing scalp EEG, the 18 signals from electrodes Fp1, F3, F7, F9, T3, T5, P3, C3, O1 from the left side and Fp2, F4, F6, F8, T4, T6, P4, C4, O2 from the right side were used. Fov EEG was recorded with 2 foramen ovale electrodes (Wieser et al., 1985), each having four contacts, manufacturing type CAD-FO-B4 (Ad-Tech Medical Instrument Corp., Wisconsin). We used an EEG-1032 amplifier system (La-Mont Medical, Inc., Wisconsin). After passing an anti-aliasing filter with a cutoff frequency of 70 Hz and an attenuation of 24 dB/oct. The EEG signals were sampled at 200 Hz and A/D conversion had a resolution of 16 bit. We used the Harmonie 5.0 software (Stellate Systems, Montreal) for EEG data acquisition. The onset of the seizure was determined by the first clinical manifestation (in the majority of the cases an epigastric aura) reported by the patient or observed by a person familiar with the recognition of mesio-temporal lobe epileptic seizure. Electroencephalo-graphically, seizure onset was defined as the first unequivocal appearance of typical continuous epileptiform activity recognized by an experienced electroencephalographer like spikes, polyspikes, spike and wave patterns, evolving and spreading low-amplitude fast or high-amplitude slow EEG rhythms, which preceded, accompanied or followed clinical signs. Short (< 2s) bursts of epileptiform EEG potentials without any symptoms or behavioral signs were not interpreted as seizures. The complete EEG recordings were visually inspected and analyzed to make sure that no seizures were missed.

We analyzed 23 EEG samples lasting 20 minutes, including at least 5 minutes pre-ictal and 5 minutes post-ictal. The samples were divided into epochs of 5 seconds.

a Recorded signals

$\omega_a, \omega_b, \omega_c, \omega_d$ are independent phases in $[0, 2\pi]$

b Fourier transform

$$Y(f) = \sum_{i=1}^N y(t) e^{-i t 2\pi f}$$

$$Z(f) = \sum_{i=1}^N z(t) e^{-i t 2\pi f}$$

c Power spectrum

Figure 1: Outline of the unresolving result provided by power spectrum analysis when the recorded signals depend on phase relations more than in frequency relations. (a) Assume that two signals, $y(t)$ and $z(t)$, were recorded simultaneously from separate channels. Each signal was recorded for N epochs of equal time. (b) Calculation of the Fourier transform of each signal. (c) Calculation of the power spectrum for each signal. See text for more details.

2.3. Data analysis

Signal analysis functions are subdivided into classes derived from their relationship with the statistical moments and cumulant series. Second order cumulant class includes correlation, power spectrum density and coherence. As second order cumulant statistics decompose the signal into a linear combination of mutually uncorrelated frequency components (Huber et al., 1971), they can be applied only to stationary signals and cannot be used to detect signal components which are in non-linear, phase dependent, relationships (Nikias and Raghuveer, 1987). Third order cumulant statistics are based on skewness. They can detect whether the signal deviates from normality, i.e. is non-Gaussian (Brillinger, 1965; Huber et al., 1971; Nikias and Raghuveer, 1987). Third order cumulant analysis include the bicoherence, the bispectrum and the bicoherence. They keep the phase relationship between the signal components and thus can detect if some of them are non linearly coupled.

Third order cumulant analysis of the electrophysiological recordings can be briefly described as follows. Firstly, let us consider a case study where an analog signal from a single channel, e.g. an EEG signal $x(t)$, is recorded during N epochs of equal duration, such that $x(t) = \sum^N (a(t) + b(t) + a(t)b(t))$ where $a(t) = \cos(2\pi f_1 t + \omega_a)$, $b(t) = \cos(2\pi f_2 t + \omega_b)$ and f_1 , f_2 represent two frequencies of periodic processes and ω_a, ω_b are phases randomly changed, i.e. uniformly distributed in $[0, 2\pi]$, for each epoch. Notice the non-linear interaction is represented by the term $a(t)b(t)$ (Fig. 1). The spectral representation of this signal $X(f)$ is obtained by the Fourier transform $X(f) = \sum^N x(t)e^{-i2\pi f t}$. The power spectrum is $P_{xx}(f) = |X(f)|^2$ and its shape will show peaks corresponding to frequencies f_1 , f_2 and $f_3 = f_1 + f_2$ (Fig. 1).

Power spectrum analysis is unable to differentiate phase relationships in recorded signals because this analysis is not sufficient to determine if the peak at frequency f_3 corresponds to a genuine non-linear interaction produced by the two oscillatory processes that interact and generate a third component or if it corresponds to an independent frequency. In order to resolve this ambiguity we compute the bispectrum B_{xxx} , defined by $B_{xxx} = \sum^N X(f_1)X(f_2), X^*(f_1 + f_2)$ where $X^*(f)$ is the conjugate of $X(f)$. B_{xxx} will be near 0 in case of independence (Brillinger, 1965), and for the peaks in the bispectrum we estimate the value of the interaction by the bicoherence C_{xxx} , defined by $C_{xxx} = |B_{xxx}|^2 / P_{xx}(f_1)P_{xx}(f_2)P_{xx}(f_1 + f_2)$.

Let us assume a case study $x(t)$ characterized by an interaction, represented by the term $a(t)b(t)$, between f_1 and f_2 so that a significant value of the bicoherence is observed for bifrequencies (f_1, f_2) . We tested the hypothesis that the bispectrum was equal to zero (Huber et al., 1971; Brillinger and Irizarry, 1998) at the 99% confidence limit to detect the significant interactions at couples of frequencies f_1 and f_2 . Phase-coupled frequencies $f_3 = f_1 + f_2$ were determined for corresponding significant bispectral analysis at couples of frequencies f_1 and f_2 . Frequency f_3 defined the ‘‘frequency of resonance’’. In order to avoid biased sampling (i.e., due to differences in gain of amplitude set for the recording from different subjects) only ten most significant peaks in bicoherence were considered here in each EEG sample.

3. Results

The bispectral analysis was performed for all channels separately in accordance to the side where the epileptogenic focus was located, in a retrospective manner after pathology was determined by magnetic resonance imagery and complementary clinical analyses. The data recorded from the four leads of one *foramen ovale* electrode were grouped together. We defined an index of resonance IR as the ratio between the relative frequency of peaks in the gamma-band (40-55 Hz) and the relative frequency of peaks in the beta-band (15-30 Hz). This means a large value of IR corresponds to a shift of f_3 towards higher frequencies (gamma-band) and a low value of IR corresponds to a shift of f_3 towards lower frequencies (beta-band).

Table 1 shows the values of IR before, during and after seizure sorted according to the ipsilateral and contralateral

Figure 2: *Foramen ovale* electrodes. Relative distribution of the frequencies of resonance before (a,b), during (c,d) and after seizures (e,f) in the ipsilateral (a,c,e) and contralateral (b,d,f) hemispheres to the epileptic focus. Bin size corresponds to 10 Hz intervals. All values refer to results obtained from *Fov* electrodes. Frequencies in range 15-30 Hz were classified in the beta band (dark grey) and frequencies in range 40-55 Hz were classified in the gamma band (light grey).

hemisphere to the epileptogenic focus. The general pattern was a decrease of IR during seizures (ictal periods) within and across patients in both hemispheres. Notice that in most locations the values of IR after seizure recovered values close to those measured in the pre-ictal period. There are two important exceptions to the general pattern of IR changes. At first, frontal leads $F3 / F4$ show only a moderate, if any, decrease of IR in the ipsilateral hemisphere but a significant increase (Chi-square test, $2p < 0.001$) of gamma-band components in the contralateral hemisphere during the ictal periods. In the latter case the value of IR after seizure tended to recover the pre-ictal level at a slower pace with respect to most locations. Secondly, central leads $C3 / C4$ in the ipsilateral hemisphere show also a tendency to an increase in IR but the significance level was barely close to 5%. In the contralateral hemisphere the pattern of IR variation for central leads $C3 / C4$ was in line with the general observation, i.e. a decrease of IR during seizure followed by a recovery close to pre-ictal levels.

The *foramen ovale* electrodes were located in the vicinity of the mesiotemporal lobe and the subsequent analysis is focused on results obtained from recordings of *Fov* EEG. Figure 2 il-

Table 1: Index of resonance (average \pm SEM) calculated before, during and after seizure in the ipsilateral and contralateral hemisphere to the epileptogenic focus. The underlined values indicate the only cases characterized by an increase of *IR* in the ictal periods.

| Lead | Ipsilateral | | | Contralateral | | |
|---------|------------------|--------------------|-------------------|------------------|--------------------|-------------------|

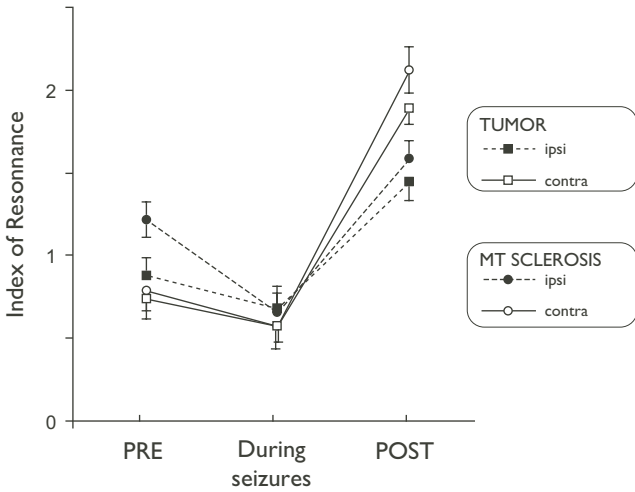

Figure 3: Scatterplot of the Index of Resonance (*IR*) before (PRE), during and after (POST) seizures for nine patients sorted out according to the hemisphere of the epileptic focus and to the etiology of the epilepsy. Mean values \pm SEM are indicated. Notice that after seizures the *IR* tended to be larger in patients affected by mesiotemporal sclerosis vs. tumor for both ipsi- and contra-lateral hemispheres.

illustrates the cumulated distribution of relative frequencies of phase coupling in the range 5 – 70 Hz for all patients grouped together and for both hemispheres. We observed a decrease of gamma activity, in particular the disappearance of any frequency of resonance higher than 55 Hz, and an increase in beta activity during the ictal periods. For both hemispheres grouped together *IR* was minimal (0.59 ± 0.08 , average \pm SEM) during seizure and maximal after seizure (1.67 ± 0.18).

The post-seizure period was the most important for the observation of a significant difference (Chi-square test, $2p < 0.05$) between *IR* calculated in the ipsilateral hemisphere to the epileptogenic area ($IR = 1.43$) vs. contralateral hemisphere ($IR = 1.95$) This difference was significant for the grouped values and consistently observed for all subjects. During the post-seizure interval *IR* tended to be larger than during the pre-

ictal period. However, in this comparison we observed a greater variability between patients and the comparison of the grouped values sorted by hemisphere was not statistically different.

A more refined analysis was attempted to investigate whether post-seizure *IR* could differentiate the patients following the etiology of the epilepsy. Two groups were formed with respect to the pathology determined after magnetic resonance imaging, as mesial temporal sclerosis ($n=4$) or tumor ($n=5$). After seizure *IR* was lower in the group of patients with a tumor, in the ipsi- as well contra-lateral side to the epileptogenic area (Fig. 3) but this tendency was not statistically significant.

4. Discussion

This study has demonstrated that non-linear analysis of *Fov* recordings by mean of bispectral analyses provides useful statistical value in localizing the side of the epileptogenic focus in patients who have medically intractable temporal lobe epilepsy. Bispectral analysis allowed us to detect significant changes in *Fov* EEG that could not be observed by second order cumulants. Our results support the hypothesis that cross-frequency coupling (Jensen and Colgin, 2007), and not merely the power of neural activity, is varied according to changes triggered by the circuits involved in the initiation of the epileptic seizures (Le Van Quyen and Bragin, 2007). Notice that we computed a single value of *IR* in each period because we looked for features that could be found in common for several patients. The value of *IR* could be calculated on shorter time scales (*e.g.* on a one-minute time base) for a detailed analysis of the evolving seizure and more complex indexes combining time varying *IR* with spectral instabilities (Aksenova et al., 2007) might represent a valid tool for further clinical assessment.

The application of bispectral analysis to monitor levels of arousal in routine clinical studies is often reduced to one patented measurement called bispectral index (BIS) provided by commercially available devices (Aspect Medical Systems Inc., Newton, MA). The BIS value (Kelley, 2007) is summing up several features of the EEG and it was advised to monitor

the depth of anesthesia (Avidan et al., 2008). However, the comparison of entropy indices with BIS revealed the limits of that technique even for monitoring anesthetic states under certain conditions (Takamatsu et al., 2006). Then, the fact that raw applications of BIS to recordings performed in epileptic patients failed to show lateralization effects (Heller et al., 2005; Ohshima et al., 2007) cannot represent an argument against the value of bispectral analysis in its whole. Actually, bispectral analysis was successfully used to detect ischemic cerebral injuries and monitor their course (Huang et al., 2007).

Our results show that the phase couplings observed in the post-ictal periods tended to occur at frequencies higher than during ictal recordings. Resonances occur as a result of interference between waves traveling in different directions that combine to form standing wave patterns (Nunez, 1995). This phenomenon requires that each neural mass has a relatively large number of synapses so that signals are transferred between two locations in a time roughly proportional to the distance between the two locations. In one-dimensional standing waves, a spatial frequency corresponds to each frequency of resonance. In multidimensional waves likely to be generated in a complex structure such as the cerebral cortex, the concept of spatial frequency is not precise but the general idea that high spatial frequencies correspond to high temporal frequencies is preserved (Nunez, 1995). Then, a decrease in the index of resonance IR , as usually observed during the ictal periods, indicate a spread of the activity over an extended cortical area. The significant difference between contralateral, with higher frequencies of resonance, and ipsilateral hemispheres clearly indicates that the index IR provides relevant information about the location of the epileptogenic focus. Indeed, the epileptogenic focus appears located in the area with lower resonant frequencies because this corresponds to the area where the seizure can propagate more easily. This appears as an interesting validation of the interpretation of IR . The observation of specific electrodes showing an opposite course of IR might reveal the transient activation/desactivation of neural circuits induced by seizure dynamics and opens the way of further investigation.

Last but not least, we shall mention the possibility to compare our results with a current source density analysis computing inverse solutions during the intervals of interest. In this case particular attention should be paid to the choice of the reference because it may affect significantly the outcome of the analysis (Hagemann et al., 2001; Tenke and Kayser, 2005). The current study was primarily aimed at comparing the results between the two hemispheres. The choice of a referential montage to two preauricular electrodes was more dictated by the willingness of computing power maps with larger total power than looking for a precise localization which would have required an ideal infinity reference (Dezhong et al., 2005).

In conclusion, the index IR appears as an interesting parameter to evaluate the level of interareal functional connectivity in Fov recordings in epileptic patients, but its usage is likely to be extended in electrophysiological studies.

Acknowledgements

The authors wish to thank the Dept. of Neurology of the Inselspital Bern, Switzerland, for providing the EEG data used for this study and in particular Dr. F. Donati and Dr. Schindler for their help in data management, and M. Kollar for assistance in EEG recording. The project was partially supported by Swiss National Science Foundation grant no. 7-IP-062620.
