HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Background

In humans, *Escherichia coli* strains can be commensal (part of the normal intestinal microbiota) and/or the cause of various infectious diseases (intestinal and extraintestinal infections) [1]. The extent of commensal or virulent properties displayed by a strain is determined by a complex balance between the status of the host and the production of virulence factors in the bacteria. The role of the intrinsic
virulence of the isolates needs to be clarified and molecular markers of virulence are required to predict the invasiveness of clinical strains isolated during the course of extraintestinal infection or patient colonization.

*E. coli* has a clonal genetic structure and exhibits a low level of recombination [2]. *E. coli* strains can be categorised into four main phylogenetic groups, A, B1, B2, and D. These groups have been defined based on proteic (multi-locus enzyme electrophoresis including the electrophoresis of esterases [3]) and genetic markers (restriction fragment length polymorphism [10]). Several studies have shown a correlation between *aes* PM and pI values, using the MaGe system [14] (esterase activity were identified, based on their respective

Seven candidate genes encoding proteins with predicted esterase B: i) a major esterase domain, ii) a theoretical pI of 4.72 for the K-12 strain protein (esterase B1, pI ranging from 4.5 to 4.8) and 5.18 for CFT073 protein (esterase B2, pI ranging from 4.85 to 5.0), and iii) the presence of a serine in the active site [9]. The inactivation of *aes* by gene disruption in K-12 MG1655 and CFT073 strains and complementation of the mutant strains with the *aes* gene confirmed that Aes was esterase B (Additional file 1: Fig. S1 and data not shown).

We then studied the correlation between *aes* sequences and esterase B electrophoretic polymorphism. The comparison of the *aes* phylogenetic tree with the theoretical and observed pI values and the esterase B electrophoretic mobilities (Mf values) for the 72 ECOR strains [10] is shown in Fig. 1. Overall analysis of the tree confirmed separation of esterase B into two variants: esterase B1 and esterase B2. Indeed, the Aes tree showed a clear distinction between Aes from the phylogenetic group B2 strains and Aes proteins from other strains, separated by a long branch, well supported by bootstrap (83%). Moreover, the characterisation of the phylogenetic group B2, based on Aes polymorphism, was consistent with the pI and Mf values of esterase B2 (pI: 4.85 to 5.0 and Mf 57 to Mf 62), which were previously demonstrated to be specific to the phylogenetic group B2. Likewise, the characterisation of the phylogenetic groups A, B1 and D, based on Aes polymorphism, correlated with the pI and Mf values of esterase B1 (pI: 4.60 to 4.80 and Mf 68 to Mf 72) [10]. Amino-acid substitutions detected from the branches of the Aes tree were analysed taking into account variation in esterase B mobility and pI values [16] (Fig. 1). In most cases, for the Aes phylogenetic group B2 strains, substitutions of acidic to neutral, neutral to basic or acidic to basic amino acids corresponded to increases in pI (from 4.85 to 5.00) and decreases in Mf values (from 62 to 57) among esterase B variants. However, there were some discrepancies. For example, the substitution of a basic amino acid in the ECOR 53 and 60 strains by a neutral amino acid in the ECOR 61 and 62 strains (R?C) corresponded to a faster migration in the ECOR 61 and 62 strains (Mf values 62 versus 60), with no effect on pI (4.85) (Fig. 1).

A more complex pattern of polymorphism was found among the A, B1 and D phylogenetic group strains. Taking the most frequent esterase B electrophoretic variant (pI: 4.60 and Mf 70) detected in the phylogenetic group A and D strains, an acidic to neutral amino-acid change (E?G) led to an increase in pI (from 4.60 to 4.75) and a decrease of Mf (from 70 to 68) of the esterase B variant, as expected. This amino-acid change was detected in 11 strains in the phylogenetic group A (Fig. 1). In contrast, several discrepancies were found among strains belonging to the phylogenetic group B1: Lys polymorphism included several substitutions of neutral to neutral ammno
acids but with increased pi values (from 4.60 to 4.75) and
in some cases paradoxical increases of Mf values (from 70 to 72) was observed (Fig. 1). These apparent discrepancies may be due to the effects of conformational or post-translational modifications of the protein.

The phylogenetic history of aes reflects the species phylogeny
To determine the evolutionary history of aes, we tested for selection using the aes sequence from 78 studied strains. First, we used a one-ratio model (M0) to estimate the aver-
age ratio \( \omega \) (dN/dS) for all sites and all lineages at 0.18. The likelihood ratio test suggested that \( \text{aes} \) was under strong global purifying selection (compared to the neutral hypothesis which is \( \omega = 0 \)). The M1a, M2a, M7 and M8 models, estimating the selection on specific codons, confirmed that the vast majority (91%) of the sites are under negative selection. Finally, the branch-site model A did not detect positive selection along the branch separating group B2 from group non-B2 strains. Thus, the use of several tests for selection has shown that the evolution of \( \text{aes} \) has been driven essentially by purifying selection, as observed for the housekeeping genes used in the MLST (data not shown); no positively selected site was identified for the branch separating esterase B2 from esterase B1 strains. Previous studies based on whole genome sequencing data using PAML have not identified \( \text{aes} \) to be under positive selection [17,18].

Visual comparison of the phylogenetic history of \( \text{aes} \) with that of the six concatenated housekeeping genes, reflecting the species phylogeny, revealed a similar topology with four main phylogenetic groups (Fig. 2). Indeed, all strains belonging to the B2 phylogenetic group were clustered in a monophyletic group (bootstrap 99%) with ECOR 66 at its base, as observed in the MLST tree. Likewise, two sub-groups were observed for phylogenetic group D, one of which was associated with the phylogenetic group B2 (ECOR 35, 36, 38, 39, 40, 41) (bootstrap 85%), also observed in the MLST tree. Phylogenetic group A also constituted two sub-groups, although these were not sister groups. By contrast, the B1 phylogenetic group was monophyletic overall, with only two strains (ECOR 4 and ECOR 47) clearly misclassified (Fig. 2).

We used a recently developed technique ("TreeOfTree") allowing the level of congruence between phylogenetic trees to be tested [19]. We tested each individual housekeeping gene tree, the MLST tree, and the \( \text{aes} \) tree. All the bootstraps are low enough (less than 67%) to suggest that all the gene trees can be viewed as not incongruent, the \( \text{aes} \) gene tree itself clustering with \( \text{pabB} \) and \( \text{trpA} \) gene trees with very low bootstrap (44%) (Fig. 3). Thus, \( \text{aes} \) tree topology showed that \( \text{aes} \) is a powerful marker of the species phylogeny, as observed for each housekeeping gene used in the MLST scheme.

\( \text{Aes B}_1 \) and \( \text{B}_2 \) protein variants were then compared by protein modelling. We found that residues S 157, D 254 and H 284 had a geometry similar to that of the esterase catalytic site. Thirty-eight polymorphic sites were identified by comparing the 319 \( \text{Aes} \) amino-acid sequences obtained for the 72 ECOR strains and six reference strains. For four of these sites, variation has become fixed in both \( \text{B}_1 \) and \( \text{B}_2 \) types, with the identified residues differing between the two types at each site. These polymorphisms could thus be used to distinguish between the types: the \( \text{B}_1 \) conserved amino acids A 53, M 64, E 73 and C 78 correspond to the \( \text{B}_2 \) conserved amino acids V, R, K and Y, respectively. These four polymorphic sites were found on the long B2/non B2 branch in the proteic tree, explaining the observed high bootstrap (83%) (Fig. 1). Fig. 4 shows the location of 24 additional sites at the protein surface with observed amino-acid variants for either type \( \text{B}_1 \) (green) or type \( \text{B}_2 \) (red). No one site was polymorphic for both \( \text{B}_1 \) and \( \text{B}_2 \) types. But for all the polymorphic sites within types \( \text{B}_1 \) and \( \text{B}_2 \), some of the amino-acid variants are shared by the two types. Consequently, these sites cannot be considered to be specific to either one type or the other and cannot be used to distinguish between the two types of protein. Polymorphic sites were clustered, localised at the surface and were not found in the active site, consistent with previous observations of similarity in the catalytic activity of \( \text{B}_1 \) and \( \text{B}_2 \) esterases with synthetic substrates [7,9]. These differences in location of the polymorphic sites between the two variants support the divergence of the B2 phylogenetic group strains from the A, B1 and D phylogenetic groups strains within this species.

Is \( \text{Aes} \) involved in virulence?

The previously observed correlation between electrophoretic esterase B polymorphism and the distinction between B2 and non-B2 phylogenetic group strains [10] and thus with the extraintestinal virulence of the strains suggested a putative role for the enzyme, or certain variants, as a virulence factor. The esterase B hydrolase function may have a direct role in the colonization or invasion of the eukaryotic cells as it was observed for esterases in other bacteria [20,21]. Indeed, esterase \( \text{B}_2 \) variants belonging to phylogenetic group B2 may confer higher levels of virulence to the strain during extraintestinal infection. There are several examples of proteins with variants playing different roles in extraintestinal infections: the adhesins \( \text{FimH} \) [22], \( \text{PapG} \) [23] and the somatic antigen O [24,25].

Previous studies of \( \text{Aes} \) have not demonstrated a role of the protein in virulence. Firstly, experimental studies characterising \( \text{Aes} \) as an enzyme with esterase activity have demonstrated the inhibitory interaction of \( \text{Aes} \) with \( \text{MalT} \), a transcriptional regulator of the maltose regulon. These findings suggested a role for \( \text{Aes} \) in the regulation of maltose metabolism [15,26]. \( \text{Aes} \) may also play a role in the regulation of raffinose metabolism by inhibiting \( \alpha \)-galactosidase [27]. However, these data were obtained from overexpression of \( \text{aes} \) from plasmids, thus raising the question of their relevance in vivo. An illustration of \( \text{aes} \) overexpression from the plasmid pACS2 [28] is shown in Additional file 1: Fig. S1. Secondly, a previous study of \( \text{aes} \) expression in the K-12 strain in vitro did not find significant effects on expression under the various metabolic,
Figure 2
Phylogenetic trees for the 72 ECOR strains and six E. coli reference strains. The trees were constructed from (A) aes sequences and (B) multi-locus sequence typing of six housekeeping genes representing the species phylogeny (trpA, trpB, pabB, putP, icd and polB) [5], obtained using PHYML procedure [50]. E. fergusonii was used as an outgroup. Bootstraps are shown for values higher than 70%. Strains studied and belonging to phylogenetic groups A (blue boxed), B1 (green boxed), B2 (red boxed), D (yellow boxed) and UG (white boxed) are indicated.
stress or environmental conditions tested [http://genexpdb.ou.edu/], with the exception of $aes$ overexpression observed in strains cultured in the presence of acetate [29]. Interestingly, esterase B exhibits Michaelis-Menten kinetics for the hydrolysis of 1-naphtyl acetate [9]. Finally, $aes$ expression was found to be homogeneous across 10 representative strains of $E. coli$/Shigella cultured in 869 medium [30].

Our previous findings from the study of the genetic sequence surrounding $aes$ did not suggest a role for the encoded protein in virulence. Indeed, comparisons, using the MaGe system, of 75 kbp of sequence upstream and downstream from $aes$ in the 20 strains of $E. coli$ [31] showed that $aes$ is not located in/or adjacent to any regions linked to extraintestinal pathogenicity specific to B2 strains (Additional file 2: Table S1).

To gain insight into Aes function we tested the mutants under different conditions. Firstly, we studied the in vitro growth of parent-type strains and their respective mutants on several carbon sources. We did not observe any difference between parent-type strains K-12 or CFT073 and their respective mutants K-12 $\Delta aes$ and CFT073 $\Delta aes$ in competition studies with LB and gluconate minimum media (data not shown). Additionally, growth of the strains CFT073, K-12, CFT073 $\Delta aes$ and K-12 $\Delta aes$, in the presence of different carbon sources, was the same for parent and mutant strains. These results suggested that Aes does not play a role in regulation of the growth of the strains in these conditions. Secondly, we studied whether Aes is involved in the virulence of $E. coli$ in vivo using a septicaemia mouse model. Kaplan-Meyer curves obtained for CFT073 and its mutants CFT073 $\Delta aes$ and CFT073 $\Delta aes$:Cm were similar, suggesting that $aes$ is not involved in the virulence process ($p = 0.87$) (Additional file 1: Fig. S2).

**Conclusion**

Selection tests and phylogenetic analyses indicate that $aes$ is under purifying selection, showing a similar evolutionary history to that of the species. The differences in electrophoretic properties between the variant types B1 and B2 were consistent with analyses of the amino-acid sequence tree for Aes and protein structure models obtained for these variants. These findings illustrated the marked divergence of the B2 phylogenetic group from the A, B1 and D phylogenetic groups in this species. This confirms the classical characteristics of esterases as excellent markers in the study of population genetics for prokaryotes, particularly Enterobacteriaceae [32], and eukaryotes such as Drosophila spp [33]. Findings from an in vivo experimental model of septicaemia did not show direct involvement of Aes in extraintestinal virulence. Moreover, we did not find any virulence-associated genes in the chromosomal region surrounding $aes$. Thus, esterase B does not appear to play

---

**Figure 3**

**Tree representing the distance matrix generated from comparisons between gene tree structures.** Gene tree structure comparisons were between trees based on $aes$ sequences, six individual housekeeping genes ($trpA$, $trpB$, $pabB$, $putP$, $icd$ and $polB$) and multi-locus sequence typing (concatenation of the six housekeeping genes), with distances derived from path-length difference. Numbers are bootstraps.
a direct role as a virulence factor in *E. coli* extraintestinal infection, but may serve as an informative marker of phylogeny.

**Methods**

**Bacterial strains**

We used *E. coli* K-12 MG1655 (phylogenetic group A) and CFT073 (phylogenetic group B2) reference strains, their mutants, K-12 Δaes (obtained from the KEIO collection [34]) and CFT073 Δaes (obtained during the course of this study) and the aes complemented mutant strains K-12 Δaes pACS2 [28] and CFT073 Δaes pACS2 for the identification of the esterase B-encoding gene. The strains K-12 MG1655, CFT073 and their aes mutants were also used for the investigation of the putative role of esterase B. We used the 72 strains from the *E. coli* reference (ECOR) collection, encompassing commensal and pathogenic strains representative of the genetic diversity of the species [35], and four additional pathogenic reference strains (536, UTI89, Sakaï and EDL 933) for the sequencing of aes. The *E. fergusonii* strain ATCC 35469T, the most closely related species to *E. coli* [36], was used as an outgroup.

**Candidate gene selection using bioinformatic tools**

The MaGe (Magnifying Genome) software program [14] was used for candidate gene selection and comparative analysis of genetic sequences surrounding aes. The MaGe software program allows gene annotation and comparative analysis of available *E. coli* and closely related genomes, with visualisation of *E. coli* genome annotations enhanced by a synchronized display of synteny groups in the other genomes chosen for comparison [14]. Protein motifs and domains can be identified using the InterPro databank [37]. Candidate genes were obtained after the selection of proteins showing esterase motifs and compatible molecular weights (from 15,000 to 60,000 Da) and pi values (from 4.0 to 5.5) [9].

**Inactivation of the aes gene and control experiments**

Inactivation was carried out as previously described [38], using a PCR product obtained with primers aesW1 (5’-TTTCATCGCGATGGGTGCTTCTTACAATGAGTAAATTGAAAGGATTTTTCGCTAGGCTGGAGCGTTC-3’) and aesW2 (5’-GCCACGGCGGAAACATCGGAATGCTGTTGCCTGCGCAATCTGATTC-3’). The PCR product contained (i) the FRT-flanked chloramphenicol acetyltransferase (*cat*) gene responsible for chloramphenicol resistance and (ii) the adjacent sequences homologous to the 5’ and 3’ flanking regions of *aes*. Inactivation of the aes gene was confirmed by PCR using the following primers: aes1 (5’-ACATCGCGGGAATGCTAAACA-3’) and aes2 (5’-ATTTAATTGTGCATGCACGCTGGAA-3’), targeting sequences upstream and downstream from the aes gene,
Complementation analysis of the mutant strains was carried out by electroporation of the multicopy plasmid pACS2 [28] containing the aes gene under its native promoter.

The esterase B phenotype was investigated by vertical slab polyacrylamide gel electrophoresis of crude extracts of parent type, mutant and complemented mutant strains, using 12% (w/v) acrylamide and discontinuous Tris/glycine buffer, pH 8.7. Esterase activity was detected by testing for the hydrolysis of 1-naphtyl acetate, as previously described [39].

Nucleotide sequencing, sequence alignments and selection tests
The aes gene was amplified by PCR, using the primers aes1 and aes2 (see above). The resulting 1250 bp PCR product was then sequenced by the Sanger method [40]. We compared aes sequences of 894 bp by sequence alignment using the ClustalW program [41]. The 72 aes sequences of the ECOR strains have GenBank accession numbers GQ167069 to GQ167140.

Amino-acid sequences deduced from the nucleotide sequences of aes were also analysed. After the generation of the maximum likelihood tree (see below), amino-acid substitutions for each branch of the Aes tree were identified by comparison of consensus sequences between different branches using the SEAVIEW program [42].

We tested for selection with code ML, implemented in PAML [43,44]. Using a maximum likelihood algorithm, PAML assigns likelihood scores to the data according to the various models of selection. Assignment of a higher likelihood score to a model incorporating selection than to a null model without selection and a significative likelihood score to a model incorporating selection than the various models of selection. The overall Ka/Ks ratio (or ω, dN/dS), reflecting selective pressure on a protein-encoding gene, was estimated using the M0 model (one-ratio) [45] for all isolate sequences, with the E. fergusonii model (one-ratio) [45] for all isolate sequences, with the E. fergusonii parent type, mutant and complemented mutant strains, polyacrylamide gel electrophoresis of crude extracts of

Tree reconstruction
Maximum-likelihood phylogenetic trees were all reconstructed using the PHYML program [50] and the GTR+G+I model. This general model is not necessarily the most parsimonious one. However, we also wanted to obtain the bootstrap support values for each partition. Given that (i) the most parsimonious model may differ from one bootstrap resampling to another, and (ii) a very long computer processing time would be required to choose the best model among the 88 possible models for each of the 500 resamplings, we chose a less time-consuming strategy, simply selecting the most general model (GTR+G+I) for all resamplings. We checked that the trees remain the same for the different models, whether the most parsimonious or the most general model is used. Additional file 2: Table S2 gives the different parsimonious models, and their estimated parameters, selected by the Akaike criterion (jMODELTEST version 0.1.1, written by Posada [51], available at http://darwin.uvigo.es/software/jmodel test.html).

Tree comparisons
We compared the phylogenetic history of aes to the phylogenetic history of the strains, based on the concatenated nucleotide sequences of six housekeeping genes (trpA, trpB, pabB, putP, ica and polB) and individual gene sequences, as described elsewhere [19]. Briefly, each phylogenetic tree Ti is firstly transformed into a tree-distance matrix Di, the distance between two strains being the number of branches with positive length connecting them along the tree. The resulting tree distance matrix Di allows the initial tree structure Ti to be recovered, independently of branch length. Two tree distance matrices (Di and Dj) (corresponding to two gene trees i and j) can be compared by calculating the Euclidian distance between them (δij) [52]. A low δij value means that the similarity between the two tree distance matrices Di and Dj is high, and, consequently, that their tree structures Ti and Tj are close. As several gene tree structures are compared through this Euclidian distance metric, a new distance matrix Δ can be built with the δij elements. This Δ matrix can then be transformed into a "tree of gene trees" using a neighbour-joining algorithm [53].

To obtain a support value for each partition of this tree, we applied this same procedure to 500 bootstrapped sets of data, obtaining 500 Δ matrices and finally, a bootstrapped consensus "tree of gene trees". A high bootstrap support value separating two sets of gene trees allows incongruent sets of gene trees to be identified; however, a low bootstrap value suggests that the two sets of trees are not incongruent or that there is insufficient phylogenetic information to reject the hypothesis of incongruence. The "TreeOffree" package is available from the website http:// /bioinformatics.lif.univ-mrs.fr.
Protein structure modelling and analysis

Modelling of the Aes protein structure was based on comparison of the available models from MODBASE [54] with models previously obtained using the Tasser-Lite homology modelling server [55,56]. Although some differences were observed between the models obtained by these two independent approaches, in particular in the N terminus region, the best models proposed by Tasser-Lite and MODBASE were similar overall. Given that our aim was to determine only the approximate location of the Aes polymorphism within the protein structure, the MODBASE model was used for further analysis. The model was finally tested to ensure that it contains an active site consistent with esterase activity. This was carried out using the 3D MSS-Sites program http://bioserv.rpbs.jussieu.fr/[57] and the Catalytic Site Atlas [58]. Polymorphic sites were identified by sequence alignment using ClustalW [41] for B1 and B2 variants separately.

Theoretical pIs of Aes were calculated using the program compute pl of the ExPASY home page http://www.expasy.ch/tools/pi_tool.html.

In vitro growth studies

Competition studies of parent strains K-12 and CFT073, with their respective mutants K-12 Δaes:Kan and CFT073 Δaes:Cm (1/1 ratio), were performed in Luria Bertani (LB) and gluconate minimum liquid media. Gluconate minimal medium mimics the intestinal environment [59]. For each medium and for each competition experiment, bacteria were plated on media with or without the appropriate antibiotic and counted after 2 h (exponential phase) and 18 h (stationary phase). Each experiment was repeated twice. Biolog GN2 (Biolog, Inc., Hayward, CA) plates were used to detect carbon utilisation of 95 substrates. Utilisation of various C sources is coupled to the reduction of a tetrazolium dye and generation of a purple colour [60]. Each strain was grown in LB medium, washed and resuspended to an optical density of 0.01 at 600 nm in mineral medium [60]. Plates were incubated at 37°C and colour changes were measured by changes in optical density (measured on a Tecan microplate reader) at a wavelength of 600 nm. The cut-off for positive results was an optical density of 0.2.

Septicaemia mouse model

A mouse model of systemic infection was used to assess the intrinsic virulence of the strains [11]. For each strain, 10 outbred female swiss OF1 mice (3-4 weeks old, 14-16 g) were challenged with a standardized subcutaneous bacterial inoculum (2 × 10⁸ CFU of E. coli). Mortality was assessed over seven days following the challenge. Assays were performed using the CFT073 strain as a positive control (killing 10/10 mice), the K-12 strain as a negative control (killing 0/10 mice) [61] and the CFT073 Δaes and CFT073 Δaes:Cm mutant strains. Data were analysed using the StatView software to obtain Kaplan-Meyer curves; statistical analysis was carried out using the logrank test, with p values < 0.05 considered as significant.

Authors' contributions

ML carried out the in silico and in vitro studies of Aes, participated to the in vivo studies of Aes and wrote the manuscript. CH contributed to the in silico studies. OC contributed to the sequencing. LG carried out in vitro studies. PD carried out tree comparisons. PT carried out the structural analysis of the protein. ED participated in the design of the study and wrote the manuscript. BP was involved in the initial design of the study and wrote the manuscript. All authors read and approved the final manuscript.

Authors' Information

ML and CH are PhD students, OC is a research engineer, LG is a technician. PD, PT, ED and BP are researchers.

Supplemental figures. A figure showing the electrophoretic patterns of esterases from various E. coli strains. Fig. S1: Polyacrylamide gel electrophoresis of Aes. Gels were stained using 1-naphthyl acetate hydrolysis to detect esterase activity. Esterases B was detected in strains. K-12 (lane 1) and K-12 Δaes pACS2 (lane 3), but not in strain K-12 Δaes (lane 2), thus confirming that aes encodes esterase B. The dilution factor used for the crude extract of the complemented strain K-12 Δaes pACS2 was 40 times greater than that of the parent and mutant strains due to overexpression of the aes gene on the plasmid. This did not allow us to detect esterase A in the complemented strain, whereas it was clearly visible for the K-12 and K-12 Δaes strains. Fig. S2: Kaplan-Meyer curves showing the comparative scores of virulence in the mouse model of septicaemia as a function of the presence or absence of Aes in the K-12 strain (blue line), CFT073 strain (green line and squares), CFT073 Δaes:Cm strain (red line and circles) and CFT073 Δaes strain (violet line and triangles).
