Abstract

Background

Patients’ personal investment and readiness to change have proved to be a prerequisite for the successful treatment of alcohol addiction. The aim of this study was to determine the contribution of cognitive functions to the motivation process to abandon maladjusted behaviour in favour of a healthier lifestyle.

Methods

An adapted version of the ‘readiness to change’ questionnaire was completed by 31 alcohol-dependent patients after detoxification and at alcohol treatment entry. This tool is designed to assess the three main stages of motivation to change regarding alcohol consumption: precontemplation (substance abuse and no intention to stop drinking), contemplation (strong intention to change habits but ambivalent behaviour) and action (cessation of excessive alcohol consumption and behavioural changes for healthier habits) stages. Patients and 37 healthy controls also underwent an extensive neuropsychological battery including episodic memory, metamemory, executive functions and decision-making assessment.

Results

When alcohol-dependent patients were considered as a group, the mean score on the action subscale was significantly higher than the precontemplation and contemplation ones. Nevertheless, when the stage of change reached by each patient was considered individually, we found that some alcohol-dependent patients were still in the earlier precontemplation and contemplation stages. Stepwise regression analysis revealed links between impaired memory and executive functions and low motivation, and between good decision-making skills and high motivation.
Conclusions

Our results suggest that a set of complementary cognitive abilities is needed to achieve awareness and resolve ambivalence towards alcohol addiction, which is essential for activating the desire to change problematic behaviour.

Keywords: Alcohol dependence; Motivation; Episodic memory; Metamemory; Executive functions; Decision-making
1. Introduction

The psychological treatment of excessive alcohol consumption requires the initiation and development of intrinsic motivation to change addictive behaviour. This can be achieved through motivational interviewing, a client-centered and directive therapeutic style that helps patients to explore and resolve their ambivalence to enhance their desire to change their behaviour (Hettema et al., 2005; Miller and Rose, 2009). High motivation is the key to patients’ engagement in clinical treatment (DiClemente et al., 1999). Prochaska and DiClemente’s ‘stages of change’ (Prochaska and DiClemente, 1983; DiClemente, 2007) model comprises different stages of motivation, including ‘precontemplation’ (substance abuse and no intention of stopping drinking), ‘contemplation’ (strong intention of changing addictive habits but ambivalent attitude) and ‘action’ (cessation of excessive alcohol consumption and adoption of previously envisaged healthier lifestyle). To progress through the different stages and adopt permanent and sustainable healthier behavioural changes, patients must implement processes of change, which are covert and overt activities and experiences in which individuals engage in order to attempt to modify risky behaviour such as consciousness raising (increasing information about unhealthy drinking behaviour) and dramatic relief (experiencing and expressing feelings about drinking behaviour). It is well known to clinicians that alcohol-dependent patients who seek treatment can be at different levels of motivation, some of them being ready to change behaviour and others being still ambivalent and resistant to modify their unhealthy habits (e.g., Carney and Kivlahan, 1995; DiClemente and Hughes, 1990; Edens and Willoughby, 2000). This heterogeneity in motivational level at treatment entry could be explained by personal and contextual factors including demographic variables, perceived stress, perceived severity of alcohol dependence and reported drinking consequences, psychiatric comorbidity, environmental quality of life and positive treatment outcome expectancies (DiClemente et al., 2009); In addition to these
previous findings, the contribution of cognitive functions to motivation to change should be
also investigated.

Even though efficient cognitive functioning would appear to promote abstinence, the
results in the literature are heterogenous. Some investigations have reported that poor
cognitive functioning may be predictive of difficulty in maintaining long-term abstinence
from alcohol (Abbott and Gregson, 1981; Allsop et al., 2000; Glenn and Parsons, 1991;
Gregson and Taylor, 1977; Miller, 1991; Noel et al. 2002; Parsons, 1994; Parsons et al., 1990;
Rourke and Grant, 1999), while others have failed to find any such link (Donovan et al., 1984;
Jin et al., 1998; Macciocchi et al., 1989; Moriyama et al., 2002; Pitel et al., 2009). However,
cognitive impairments could indirectly influence clinical outcomes (abstinence or relapse) by
affecting the influence of readiness to change, as several studies have highlighted a strong
relationship between motivation to change and drinking outcome (Penberthy et al., 2007;
Project MATCH Research Group, 1997, 1998). While several studies have investigated a
potential association between cognitive functioning and treatment outcome (abstinence or
relapse), few researchers have considered the relationships between cognitive functioning and
motivation to change. Intellectual functioning, memory and executive skills have predicted
greater motivation to change substance use including alcohol use among people with severe
co-occurring mental disorders (Blume et al., 1999) and among college students with drinking
problems (Blume et al., 2000). In addition, Severtson et al. (2010) demonstrated an
association between executive functioning and motivation to enter treatment among regular
users of heroin and/or cocaine. Although episodic memory (Fama et al., 2004; Pitel et al.,
2007), executive functions (Sullivan et al., 2000; Moselhy et al., 2001; Pitel et al., 2007),
metamemory (Le Berre et al., 2010) and decision-making (Goudriaan et al., 2005; Noel et al.,
2007) are all known to be impaired in alcohol-dependent patients, only one study (Blume et
al., 2005) examined the relationships between episodic memory, executive functions and the
readiness to change drinking behaviour, as assessed by the ‘readiness to change’ questionnaires (RTC; Rollnick et al., 1992), in alcohol-dependent patients who met either the criteria for alcohol abuse or dependence but were not in treatment. This preliminary study revealed links between motivation stages and verbal memory scores but did not show a relationship with executive abilities, in accordance with another study conducted within the same clinical population (Blume et al., 2009). Further studies are now required to determine the specific memory components (learning, encoding, retrieval or recollection) which might be associated with readiness to change. in alcohol-dependent patients at treatment entry.

The aim of the present study was therefore to define the cognitive factors that might, at least partially, predict the motivational evolution to change drinking behaviour. To this end, we measured motivation with the RTC and assessed a range of neuropsychological functions, including episodic memory and executive functions and higher level cognitive functions such as metamemory and decision making.

2. Materials and Methods

2.1. Participants

Two groups of participants were included in this study: 31 chronic alcohol-dependent patients (mean age: 43.9 ± 7 years; range: 31-56) and 37 controls (mean age: 45.5 ± 6.1 years; range: 31-60) matched for age and education. There were 25 men in the control group and 26 men in the alcohol-dependent group. Alcohol-dependent patients were early in abstinence from alcohol (mean days of sobriety before inclusion: 12.64 ± 7.16; range: 7-40).

Age, education level and Mini Mental State Examination (MMSE, Folstein et al., 1975), depression level and anxiety level scores are summarized in Table 1.

Performances on the MMSE were significantly poorer in the chronic alcohol-dependent patients than in the controls. The depression level, measured with the self-
administered Beck Depression Inventory (BDI, Beck et al., 1961), was higher in the alcohol-dependent group than in the control group. Similarly, anxiety, measured with the State-Trait Anxiety Inventory (STAI, Spielberger et al., 1983), was higher in the alcohol-dependent group. Demographic and clinical data for patients and controls are summarized in Table 1.

Insert Table 1

Alcohol-dependent participants were recruited by clinicians on the basis of the DSM-IV criteria for alcohol dependence (American Psychiatric Association, 1994) while they were receiving treatment for alcohol dependence as in-patients at Caen University Hospital. Patients had no history of other types of substance dependence (except tobacco), and they had already completed detoxification when they were included in the study. They were interviewed to constitute a review of their alcohol use history and typical use patterns prior to treatment including the length of alcohol-dependence and their usual daily alcohol intake over the six months prior to treatment (Table 1). None of the participants was taking psychotropic medication, displayed psychiatric problems or had any history of pathology (head injury, coma, epilepsy, Wernicke’s encephalopathy, cirrhosis or depression) that might have affected their cognitive functions. Control participants were interviewed to confirm they did not drink more than 21 (men) or 14 (women) weekly standard drinks and no more than four at a time (World Health Organization criteria). Prior to inclusion, all the participants filled in a health questionnaire including questions about alcohol and drug consumption. None of the controls had a history of drug abuse. All the participants gave their informed consent to the study, which was approved by the local ethics committee.
2.2. Materials and procedure

2.2.1. ‘Readiness to change’ (RTC) questionnaire

We used an adapted version of the RTC (Rollnick et al., 1992) self-report questionnaire to assess motivation and readiness to change alcohol abuse behaviour. Based on the stages of change model (Prochaska and DiClemente, 1983), it is made up of 12 questions divided into three subscales, each corresponding to a stage of change (4 questions per subscale). These three subscales correspond to the precontemplation stage (“It’s a waste of time thinking about my drinking”), the contemplation stage (“I enjoy my drinking but sometimes I drink too much”) and the action stage (“Anyone can talk about wanting to do something about their drinking but I am actually doing something about it”). Patients were asked to rate their agreement with statements about their alcohol consumption on a 5-point Likert-type scale ranging from ‘strongly disagree’ (-2) to ‘strongly agree’ (+2). We took the patients’ scores on each subscale (ranging from -8 to 8) as our variables. The subscale with the highest score indicated which motivational stage the patient had reached at the time of the testing. When two or more subscale scores were equal, we considered that the scale farthest along the continuum of change (precontemplation-contemplation-action) represented the patient’s stage of change. The interpretation of the motivation measures must be done as follow. A higher score on action subscale than on precontemplation and contemplation subscales refers to high level of motivation. Inversely, a higher score on precontemplation and contemplation subscales than on action subscale refers to low level of motivation.

2.2.2. Neuropsychological assessments (a description of each task is provided in the online Table SM1)

Episodic memory

We assessed episodic memory with the Free and Cued Selective Reminding Test (FCSRT) (Grober and Buschke, 1987; Grober et al., 1988) for verbal learning abilities. The state of consciousness associated with memories, together with encoding and retrieval skills,
was measured with the Spondee test (Pitel et al., 2007), which includes the Remember-Know paradigm (Gardiner et al., 2002).

**Metamemory**

We assessed metamemory with the “Feeling-of-Knowing” (FOK) task (Pinon et al., 2005; Le Berre et al., 2010). After learning 20 cue-target pairs and prior to a recognition task, participants were asked to say whether they thought they would recognize the target afterwards. An episodic FOK accuracy measure was then calculated (Goodman-Kruskal gamma, Nelson, 1984) to assess the agreement between predicted and actual recognition performance.

**Executive functions and decision-making**

We assessed executive functions with a verbal fluency task (Cardebat et al., 1990; adapted version by the Groupe de Réflexion pour l’Evaluation des Fonctions EXécutives (GREFEX), Godefroy O, 2001) for spontaneous flexibility abilities and strategic search in memory, the Trail-Making Test (Reitan, 1958; adapted GREFEX version) Part B for reactive flexibility, the Stroop test (Stroop, 1935; adapted GREFEX version) for inhibition, the Hayling test (Burgess and Shallice, 1996; French adapted version by Meulemans et al., 2001) for semantic inhibition, the Modified Card Sorting Test (MCST) (Nelson, 1976; adapted GREFEX version) for cognitive flexibility, working memory, problem-solving and set-shifting abilities, and the Iowa Gambling Task (Bechara et al., 1994) for decision-making. These are well-established tests and detailed descriptions of them are widely available (Lezak et al., 2004).

**2.3. Statistical analysis**

We analysed the data in four steps. First, we conducted a group analysis to describe the motivational features of the alcohol-dependent group as a whole, applying a paired-samples $t$-test to the three RTC subscale scores. In addition, we analysed individual
motivation profiles to find out which stage of change each patient was, according to the RTC subscale with the highest score. Second, we investigated the effects of alcohol-dependence on episodic memory, metamemory, executive functions and decision-making skills, using an unpaired two-sample t-test. Third, in order to identify the potential effect of confounding factors (age, education, drinking history MMSE score and anxiety or depression levels), we calculated Pearson’s correlation coefficients in the alcohol-dependent group between these factors and each motivation subscale score. Factors identified as being significantly correlated (p < .05) with motivational data were included as covariates in a subsequent stepwise regression analysis. Fourth, a stepwise regression analysis was carried out in the alcohol-dependent group to examine the best cognitive predictors of each RTC subscale score among episodic memory, metamemory, executive and decision-making scores. A probability level of .05 was adopted for all analyses.

3. Results

3.1. Readiness to change

Group analysis: The mean score on the action stage subscale was higher than the mean scores on both the precontemplation, \( t(30) = -11.01, p < 0.001 \), and contemplation stage subscales, \( t(30) = -4.18, p < 0.001 \) (Table 2).

Individual analyses: 21 alcohol-dependent patients scored highest on the action subscale, nine on the contemplation subscale and one on the precontemplation subscale.

3.2. Effects of alcohol-dependence on episodic memory, metamemory, executive functions and decision-making faculties

Results revealed that alcohol-dependent patients performed more poorly than controls on all the verbal episodic memory tasks (learning, encoding, retrieval and recollection), as
well as on the metamemory measure, the executive tasks (reactive flexibility, inhibition, cognitive flexibility, working memory, problem-solving and set-shifting) and the decision-making measure. Data are summarized in Table 3.

3.3. Confounding variables

As age, education, MMSE scores, psychiatric scores and drinking variables did not correlate with the precontemplation and contemplation subscale scores in the alcohol-dependent group, these variables were not included in the stepwise regression analyses for these stages. Only alcohol intake was entered as a covariate in the stepwise regression analysis conducted with the action stage score, as this drinking variable was significantly correlated with it \( (r = -0.40, p = 0.03) \). Detailed results of the correlations are provided in Table 4.

3.4. Cognitive predictors of readiness to change

Precontemplation subscale: The only cognitive predictor for the precontemplation subscale score was the level of consciousness associated with recollection (mean percentage of ‘Remember’ answers), which accounted for 20% of the variance. A lower state of consciousness significantly predicted higher precontemplation subscale scores \( (r = -0.44, p = 0.01) \) (Fig. 1A and Table 5).

Contemplation subscale: In the first step, 23% of the variance in contemplation subscale score was accounted for by the time spent on the Stroop interference task. The second cognitive predictor making a significant contribution to contemplation subscale score was the number of errors for the Modified Card Sorting Test (MCST) (accounting for 15% of the variance). Higher Stroop Color-Word time score and higher MCST number of errors scores
significantly predicted higher contemplation subscale scores ($r = 0.48, p = 0.006$) and $r = 0.46, p = 0.01$ respectively) (Figure 1B and Table 5).

*Action subscale:* The only cognitive predictor for the action subscale score was the decision-making measure, which accounted for 19% of the variance. Higher decision-making scores significantly predicted higher action subscale scores ($r = 0.43, p = 0.01$) (Fig. 1C and Table 5).

Insert Fig. 1 and Table 5

### 4. Discussion

The main objective of our study was to improve our understanding of how cognitive abilities are involved in the motivation to change addictive behaviour. More specifically, we investigated the basic and higher-level cognitive functions that are known to be impaired in alcohol-dependence to explain – at least in part - why some patients have difficulty shifting from a low level of motivation to a high level of motivation. To this end, we focused our attention on the effect of episodic memory, metamemory, executive function and decision-making abilities on motivation in alcohol-dependent patients early in abstinence and at clinical treatment entry.

Concerning readiness to change for the alcohol-dependent group as a whole, the mean score on the action subscale was significantly higher than the precontemplation and contemplation mean scores. This observation is not surprising, given that those patients were at alcohol treatment entry. Nevertheless, when we adopted a more qualitative approach, investigating the stage of change reached by each individual patient, we found that some patients were still in the earlier precontemplation and contemplation stages. This finding is in accordance with clinical observation that not every patient is highly motivated to change at treatment entry (e.g., Carney and Kivlahan, 1995; DiClemente and Hughes, 1990; Edens and
Moreover, alcohol-dependent patients performed more poorly than controls on the cognitive tasks, in agreement with previous studies showing episodic memory impairment (Beatty et al., 1995; Fama et al., 2004; Goldstein et al., 2004; Pitel et al., 2007), executive dysfunction (Fama et al., 2004; Noel et al., 2001; Pitel et al., 2007; Tedstone et Coyle, 2004), metamemory decline (Le Berre et al., 2010) and decision-making deficit (Goudriaan et al., 2005; Noel et al., 2007) in these patients. Our results also revealed a relationship between verbal episodic memory impairment, more specifically a deficit of conscious recollection (Pitel et al., 2007), and high precontemplation scores, as well as relationships between weak executive performances and high contemplation scores, and between good decision-making skills and high action scores.

These findings suggest that patients with higher episodic memory abilities would have greater intention of changing their high-risk behaviour in the near future. More particularly, our data showed an association with a specific episodic memory score: the ‘R answers’. This measure refers to conscious recollection involving retrieval of a personal event and features about its encoding context (Gardiner et al., 2002). We can assume that higher episodic memory functioning promotes patients’ engagement in the ‘consciousness-raising’ process. This hypothesis is supported by the findings of Blume et al. (2005) suggesting that intact verbal memory performance favours awareness of difficulties arising from alcohol consumption. ‘Consciousness-raising’ refers to an increase in the level of awareness about the origins, consequences and treatment possibilities of inappropriate behaviour such as excessive alcohol consumption. It is achieved when patients are able to access information about alcohol-dependence to supplement their own knowledge about their disease.

Moreover, during the contemplation stage, patients need to complete a ‘decisional balance’ (Janis and Mann, 1977) evaluating the perceived advantages and disadvantages of consuming alcohol or quitting drinking. This ‘decisional balance’ enables them move on to
the next stages of change. Alcohol-dependent patients are ambivalent and oscillate between
their impulsive ‘limbic’ behaviour and more controlled behaviour subtended by frontal lobe
activity (Crews and Boettiger, 2009). Our study revealed that patients with lower motivation
to change also had lower executive functioning including deficits of inhibition, mental
flexibility, problem-solving and rule abstraction. These findings suggest that efficient
executive functioning is necessary to go through “decisional balance”.

Finally, our statistical analysis demonstrated a relationship between higher decision-
making abilities and higher action stage scores. This observation could imply that patients
early in abstinence who have problems making decisions (Noel et al., 2007) experience
greater difficulty resolving decisional balance and moving towards a strong desire for change.
They must hone their decision-making faculties in order to detect risks related to alcohol in
the everyday life situations. They also have to glean information about causes and outcomes
from past experiences and project themselves into the future. However, some patients who are
addicted to alcohol or other substances and who have decision-making disorders may have
difficulty anticipating the future. They prefer choices that bring an immediate benefit, even if
they are harmful in the long term (loss of work and family or social deterioration) (Bechara et
al., 2001; Bechara et al., 2002; Goudriaan et al., 2005; Noel et al., 2007).

To sum up, cognitive performance may predict the level of motivation of alcohol-
dependent patients at treatment entry and must be taken into account in clinical decisions.

Clinical implications and limitations

High cognitive functioning including efficient episodic memory, executive functions
and decision-making abilities seems essential to enhance readiness to change drinking
behaviour. The neuropsychological screening of possible cognitive impairments may prove to
be extremely useful at alcohol treatment entry and have to be taken into account to make
relevant clinical decisions and choose the most appropriate treatment according to the patients’ level of motivation. As a consequence of their cognitive deficits, some alcohol-dependent patients may not be able to undergo the standard treatment in an addictology department because of their low motivation. In alcohol-dependence, several studies have shown that cognitive disorders are at least partly reversible with abstinence (Rourke and Grant, 1999; Pitel et al., 2009). Therefore, once patients have physically completed detoxification, it may be a good idea to favour the neuropsychological recovery of those who display cognitive deficits by extending the period they spend without alcohol (e.g., in-patient follow-up rehabilitation) before being admitted to the addictology department. It would also be interesting to promote spontaneous neuropsychological recovery by using rehabilitation techniques used with brain-injured patients.

One of the limitations of this study is that it was carried out with a very particular sample of alcohol-dependent patients, as our aim was to explore readiness to change at a specific point in the clinical course of alcohol dependence (i.e., at alcohol treatment entry, early in abstinence). Although we are sure that cognitive performance was not influenced by acute alcohol consumption, our findings cannot, nevertheless, be extended to the general clinical population of alcohol-dependent patients. Therefore, other studies are needed to provide information about the link between motivation and cognitive skills in patients with alcohol abuse or dependence who are not receiving clinical treatment and who continue to drink alcohol. Another limitation is that as the gender distribution of our alcohol-dependent group reflected the gender distribution that prevails in most alcohol treatment departments in France, our results are mainly representative of alcohol-dependent men. Moreover, although the lack of motivation could partly be explained by cognitive impairment, the move towards higher readiness to change relies on many processes of change which, in turn, rely not only on higher-level cognitive functions but also on emotional and social skills including theory of
mind, empathy and self. Further studies are therefore needed to assess the possible
impairment of social cognition in alcohol-dependence and the latter’s links – if any - with the
multidimensional phenomenon of motivation.
