Abbreviations: 4-HHE, 4-hydroxy-2-hexenal; 4-HNE, 4-hydroxy-2-nonenal; NF-κB, Nuclear Factor kappaB; GPx2, gastrointestinal glutathione peroxidase 2; GRP78, glucose-regulated protein 78; IL, interleukin; MCP-1, monocyte chemotactic protein-1; DHA, docosahexaenoic acid; TG, dietary triacylglycerols; PL, phospholipids; TAG: plasma triacylglycerols; ER, endoplasmic reticulum; HF, high-fat; BLM: basolateral medium; Lyz-1: lysozyme 1.

ABSTRACT

Dietary intake of long-chain *n*-3 PUFA is now widely advised for public health and in medical practice. However, PUFA are highly prone to oxidation, producing potentially deleterious 4-hydroxy-2-alkenals. Even so, the impact of consuming oxidized *n*-3 PUFA on metabolic oxidative stress and inflammation is poorly described. We therefore studied such effects and hypothesized the involvement of the intestinal absorption of 4-hydroxy-2-hexenal (4-HHE), an oxidized *n*-3 PUFA end-product.

In vivo, 4 groups of mice were fed for 8 weeks high-fat-diets containing moderately oxidized or unoxidized *n*-3 PUFA. Other mice were orally administered 4-HHE and euthanized postprandially *vs* baseline mice. *In vitro*, human intestinal Caco-2/TC7 cells were incubated with 4-hydroxy-2-alkenals.

Oxidized diet increased 4-HHE plasma levels in mice (up to 5-fold, $P < 0.01$) compared with unoxidized diet. Oxidized diet enhanced plasma inflammatory markers and activation of NFkappaB in the small intestine together with decreasing Paneth cell number (up to -19% in the duodenum). Both *in vivo* and *in vitro*, intestinal absorption of 4-HHE occurred associated with 4-HHE-protein adducts and increased expression of glutathione peroxidase 2 (GPx2) and glucose-regulated protein 78 (GRP78).

Consumption of oxidized *n*-3 PUFA results in 4-HHE accumulation in blood after its intestinal absorption and triggers oxidative stress and inflammation in the upper intestine.

INTRODUCTION

Chronic inflammation and oxidative stress are now recognized as major factors involved in the pathogenesis of several current diseases such as overweight, obesity and cardiovascular diseases (1-3). Elevated levels of pro-inflammatory cytokines and chemokines, such as interleukins (IL) and monocyte chemoattractant protein-1 (MCP-1), are hallmarks of the metabolic syndrome (1, 2). Several studies demonstrate the nutritional benefits of consuming long-chain (LC) *n*-3 PUFA from fish, in particular docosahexaenoic acid (DHA, 22:6 *n*-3) and eicosapentaenoic acid (EPA, 20:5 *n*-3) to protect against several pathologies (4-7). Therefore, nutritional recommendations in Western societies have been established for *n*-3 PUFA intake, of 500 mg/day of EPA and DHA, to achieve nutrient adequacy and reduce incidence of chronic diseases, particularly cardiovascular diseases (8).

However, current studies reveal that the *n*-3 PUFA may not be devoid of risk. Possible harmful effects of high levels of *n*-3 PUFA on retinal membrane degeneration have been described by Tanito et al (9). Therefore, dietary LC *n*-3 PUFA are highly vulnerable to oxidation, which is one of the major problems in food chemistry and may decrease their nutritional value. Indeed, peroxidation causes loss of nutritional quality and further leads to the generation of genotoxic and cytotoxic compounds such as the 4-hydroxy-2-alkenals (10, 11). 4-Hydroxy-2-hexenal (4-HHE) and 4-hydroxy-2-nonenal (4-HNE) are major end-products derived from *n*-3 and *n*-6 PUFA peroxidation, respectively. In addition to being markers of lipid peroxidation *in vivo*, 4-HNE and 4-HHE induce noxious effects on biological systems. These lipid aldehydes are prone to react with thiols and amines moieties and make Schiff base and/or Michael adducts with biomolecules such as proteins, DNA and phospholipids (12, 13). Numerous studies reported the genotoxicity and cytotoxicity of these 4-hydroxy-2-alkenals in pathophysiological contexts on tissues and

cells (14-16), but nothing is known to date about the possible contribution of 4-hydroxy-2-alkenals being present in food products, their fate after ingestion and metabolic effects.

In this context, the intestinal tract represents the first barrier of detoxification and of defense against oxidative stress. Thus, intestinal cells can be exposed to oxidized PUFA or to lipid peroxidation end-products. However, evidence is lacking to support unfavorable health effects of dietary oxidized *n*-3 PUFA and demonstrate their possible role in the generation of oxidative stress and inflammation. Furthermore, limited data is available to support the hidden assumption of intestinal absorption of dietary lipid oxidation by-products.

Therefore, we hypothesized that long-term intake of limited amounts of oxidized *n*-3 PUFA in high-fat (HF) diets could exert harmful health effects, due to the absorption of their end-products such as 4-HHE by the small intestine; the end-products having been formed during the processing, storage and/or final handling of foods or after their ingestion. The aim of the present study was thus to investigate (i) the effects of oxidized *n*-3 PUFA diets compared with unoxidized diets on oxidative stress and inflammation in mice and (ii) the possible implication of the intestinal absorption of some PUFA oxidation end-products, namely 4-hydroxy-2-alkenals, through their effects on intestinal stress and inflammation, *in vivo* and *in vitro*. Because several types of LC *n*-3 PUFA sources are present in human food, we tested lipid mixtures containing EPA and DHA carried by either triacylglycerols (TG) or phospholipids (PL). Moreover, we analyzed different segments of the absorptive intestinal epithelium, especially the duodenum before the interaction with bile salts occurs and the jejunum that represents the major site of lipid absorption, but also the ileum to test whether some effects remain in this more distal segment.

MATERIALS AND METHODS

Materials

4-HHE and 4-HNE and trideuterated compounds were synthesized according to Soulère et al. (17). Omegavie® Tuna oil 25 DHA-flavorless, as a source of triacylglycerol rich in long-chain *n*-3 fatty acids (TG-DHA, 26% of DHA), lecithin rich in DHA (PL-DHA, 41% of DHA) and kiwi seed oil were provided by Polaris (Pleuven, France). Lard was supplied by Celys (Rezé, France), sunflower oil was from Lesieur® (Asnières-sur-Seine, France) and oleic sunflower oil from Olvéa (Marseille, France). Vegetable lecithin rich in linoleic acid 18:2 *n*-6 (PL-LA) was from Lipoid (Frigenstrasse, Germany).

Preparation of unoxidized and oxidized lipid blends and mice diets

Four lipid blends were prepared at the lab scale to obtain similar fatty acid composition and quantities in the four diets and similar amounts of glycerophospholipids and triacylglycerols. In these blends, DHA was supplied either in the form of triacylglycerols (TG diet) or phospholipids (PL diet), i.e., the name chosen for the diets reflects the type of molecules that carry long-chain *n*-3 PUFA in the diet. The oxidized lipid blends (TG-ox and PL-ox respectively) were prepared as described as follows: primary lipid mixtures for PL and TG groups were prepared with a small proportion of lard to maintain oxidability of PUFA. These preliminary oil mixtures were dispersed in 30% w/w relative to aqueous phase (mineral water; Evian) to prepare oil-in-water emulsions. The emulsions were then kept at 50°C in the dark with continuous shaking until oxidation level was considered as sufficient according to our previous experiments (estimated α -tocopherol contents of the blends decreased by 50%). Oxidized emulsions were then lyophilized and the resulting oxidized lipid mixtures completed with the necessary quantity of lard to reach the required final composition of lipid blends. The composition of the four diets is reported in **Table 1**.

Animals and diets

Male C57BL/6 mice (8 wk, 20g) were from Janvier SA (Le Genest Saint-Isle, France) and were housed in a temperature-controlled room (22°C) with a 12 h light/12 h dark cycles. After 2 weeks of chow diet, mice were randomly divided into four groups of 12 mice and fed one of the 4 high-fat diets containing *n*-3 PUFAs: unoxidized groups: PL, TG; oxidized groups: PL-ox, TG-ox. Animal experiments were performed under the authorization n°69-266-0501 (Direction Départementale des Services Vétérinaires du Rhône). All experiments were carried out according to the guidelines laid down by the French Ministry of Agriculture (n° 87-848) and the E.U. Council Directive for the Care and Use of Laboratory Animals of November 24th, 1986 (86/609/EEC), in conformity with the Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals. COS holds a special licence (n° 69266257) to experiment on living vertebrates issued by the French Ministry of Agriculture and Veterinary Service Department. Body weight was measured twice weekly and food intake was measured weekly. After 8 weeks, mice were euthanized by intraperitoneal (IP) injection of sodium pentobarbital. Plasma, liver, white adipose tissue and small intestine mucosa were collected.

Caco-2/TC7 cell culture and treatment

Caco-2/TC7 cells, which are the widely used *in vitro* model of human origin to test intestinal absorption of lipids, were provided by Monique Rousset (Centre de Recherche des Cordeliers, Paris, France) and used between passage 35 and 45. Cells were seeded in 75-cm² flasks (Falcon, Becton Dickinson) until 80–90% confluence. They were grown in complete DMEM (Gibco) supplemented with 20% heat-inactivated FBS (Gibco), 1% non-essential amino acids (Gibco) and 1% antibiotics (penicillin/streptomycin, Gibco), and maintained under a 10% CO₂ atmosphere at 37°C. For experiments, cells were seeded at a

density of 25×10^4 cells per filter on microporous (0.4 μm pore size) polyester filters (Transwell, Corning, USA) and grown to confluence in complete medium, which was routinely reached 7 days after seeding. The cells were used 21 days after seeding. Monolayers were incubated with 4-HHE or 4-HNE in the apical compartment (1 to 100 μM brought in DMSO at 0.5% in the final medium) and the basolateral compartment receiving serum-free DMEM. After incubation, basolateral media and cells were collected.

Animal treatment with 4-HHE

After an overnight fast, three groups of 4 male C57/BL6 mice (8 weeks, 22 g) were given a single application of 4-HHE diluted in water *via* 0.5% DMSO by oral gavage at a dosage of 10 mg/kg b.w. and were sacrificed 1, 2, 4 h after gavage. A fourth group of mice was sacrificed immediately after gavage for the baseline control. For sacrifice, mice were anesthetized by IP injection of pentobarbital (35 mg/kg) and blood was collected by cardiac puncture with heparinized syringes. Plasma and small intestine mucosa (duodenum and jejunum) were collected.

4-Hydroxy-2-alkenals: derivatization, analysis and quantification

4-hydroxy-2-alkenals were derivatized from 400 μl of basolateral media of Caco-2/TC7 or from 300 μl of plasma as described previously (18). Deuterated 4-HNE and 4-HHE (20 ng) used as internal standards were added to the samples. Briefly, they were treated with O-2,3,4,5,6-pentafluorobenzyl hydroxylamine hydrochloride. After acidification with H_2SO_4 , pentafluorobenzyl oxime derivatives were extracted with methanol and hexane. The hydroxyl group was then converted into trimethylsilylether after an overnight treatment with *N,O*-bis(trimethylsilyl)trifluoroacetamide at room temperature. The pentafluorobenzyl oxime trimethylsilylether derivatives of 4-HHE (O-PFB-TMS-4-HHE)

and 4-HNE (O-PFB-TMS-4-HNE) were then analyzed by GC-MS using negative ion chemical ionization (NICI) mode on a Hewlett-Packard quadrupole mass spectrometer interfaced (18) with a Hewlett-Packard gas chromatograph (Les Ullis, France).

IL-6 and MCP-1 measurements

IL-6 and MCP-1 (Clinisciences, France) were assayed by ELISA kit according to the manufacturer's instructions.

Plasma triacylglycerols and NEFA measurements

Plasma triacylglycerols (TAG) were measured with the triglyceride PAP kit (BioMérieux France) as previously described (19). Plasma TAG concentration was calculated by subtracting the free glycerol in plasma measured with the glycerol UV-method (R-Biopharm/Boehringer, Mannheim, Germany). Plasma NEFA was measured using NEFA-C kit (Wako Chemicals, Neuss, Germany) (19).

Fatty acid analysis

Total lipids were extracted from 35 μ L of plasma as described previously (19). The organic phase was evaporated under N₂ and total fatty acids were transesterified using boron trifluoride in methanol (BF₃/methanol) (19). The FA methyl esters were then analyzed by GC using a DELSI instrument model DI 200 equipped with a fused silica capillary SP-2380 column (60 m x 0.22 mm). Heptadecanoic acid (C17:0, Sigma, France) was used as an internal standard.

Quantification of free malondialdehyde (MDA) and hydroperoxides in oil mixtures

Thiobarbituric acid–MDA adducts were separated using a method adapted from different authors (20, 21) by HPLC and measured by fluorimetry using an external calibration curve (excitation 535 nm, emission 555 nm). Hydroperoxides were quantified in lipid blends according to a method adapted from Nourooz-Zahed et al (22).

Quantitative PCR Analysis

Total RNA was extracted from Caco-2/TC7, duodenum, jejunum and ileum of mice using the NucleoSpin[®] RNA/Protein kit (Macherey Nagel, Duren, Germany). cDNAs were synthesized from 1 µg of total RNA in the presence of 100 units of Superscript II (invitrogen) with a mixture of random hexamers and oligo (dt) primers (Promega, Charbonnières, France). The amount of target mRNAs was measured by RT, followed by real-time PCR, using a Rotor-Gene Q (Qiagen, France). The amount of target mRNAs was measured by RT, followed by real-time PCR, using a Rotor-Gene Q (Qiagen, France). Primer sequence and RT-quantitative PCR conditions are available upon request (cyrille.debard@univ-lyon1.fr). Hypoxanthine guanine phosphoribosyl transferase (HPRT) mRNA level and TATA-box Binding Protein (TBP) mRNA were used to normalize data of duodenum, jejunum and Caco-2/TC7 cells, respectively.

Western blot analysis

Total proteins from Caco-2/TC7 and jejunum of mice were extracted with the NucleoSpin[®] RNA/Protein kit (Macherey Nagel). A total of 40 µg of protein from each sample were subjected to 10% SDS-PAGE and transferred to a polyvinylidene fluoride (PVDF) membrane. Membranes were blocked with kit reagent and incubated overnight with antibodies according to the manufacturer's recommendations. Antibodies against total NF-

κ B P65 and phospho-NF- κ B P65 (Ser 529) were obtained from Signalways Antibody (Clinisciences, France); Phospho-I κ B α (phosphoS32+S36) was from abcam (Cambridge, UK) and β actine was from Sigma, France. After incubation with secondary antibody, blots were developed with a commercial kit (WesternBreeze Chemiluminescent, Invitrogen, France). Quantification was performed by densitometry analysis of specific bands on immunoblots with Quantity One software (BioRad, Marne-la-Coquette, France).

Immunohistochemistry

Duodenal tissues were removed, fixed in 90% ethanol for 24 h at -20°C and processed into paraffin. Serial paraffin sections (4 μ m) were rehydrated and endogenous peroxidase activity was quenched with 20 min incubation in 5% H₂O₂/PBS. After incubation in 2.5% normal horse blocking serum (Impress™, Vector), sections were incubated for 60 min at room temperature with anti-lysozyme (1/100, Zymed Laboratories) antibody diluted in blocking solution. The immune reactions were then detected by incubating with a ready-to-use peroxidase-labelled secondary reagent, ImmPRESS (MP-7401 for rabbit antibodies, Abcys, Paris, France) (30 min, room temperature). Control experiments were performed simultaneously omitting the primary antibody or incubating with preimmune rabbit serum. The sections were then counterstained and mounted.

Quantitative analysis for Paneth cells

The Paneth cell lineage was analyzed by assessing the percentage of crypt cross sections with Paneth cells (per 80 crypts). For this purpose, 4-6 sections were analyzed per mouse. A crypt was considered when it was cut along or nearly along the length of the crypt lumen (at least two-thirds of the length of the crypt). All slides were analyzed by a single investigator who was blinded to the treatment groups.

Protein carbonyl content

Protein carbonyl content was determined with an Oxyblot Oxidized Protein Detection Kit from Chemicon (Hampshire, UK). The carbonyl groups in the protein chains were derivatized into dinitro-phenyl-hydrazone by reaction with dinitro-phenyl-hydrazine (DNPH) according to the manufacturer's instructions. After the derivatization of the protein sample (20 µg), one-dimensional electrophoresis was carried out on a 10% SDS-PAGE gel, proteins were transferred to PVDF membranes. After incubation with anti-DNP antibody, the blot was developed with a chemiluminescence detection system. The intensity of each line was measured and normalized by mean control levels.

Dot blot analysis

50 µg of total proteins from Caco-2/TC7 cells or from duodenum and jejunum of mice were spotted onto nitrocellulose membrane. Blocked membrane was incubated overnight with anti-HNE-adducts (Calbiochem 393207, San Diego, USA) or anti-HHE-adducts (CosmoBio N213730-EX, Tokyo, Japan) antibodies. Blots were developed with a commercial kit (WesternBreeze Chemiluminescent, Invitrogen, France). The quantification was performed by densitometric analysis of specific spots on immunoblots using Quantity One software.

Statistical analysis

All data are presented as means \pm SEM and were analysed using Statview 5.0 software (Abacus Concept, Berkeley). One-way ANOVA followed by Fisher PLSD was used (i) For the dietary study to compare PL, PL-ox, TG and TG-ox groups, (ii) for the gavage study, to compare plasma alkenal concentrations as a function of time and (iii) for the Caco-2 cell studies, to compare treatment effects. Two-way ANOVA followed by Fisher PLSD was

used to compare oxidized vs. unoxidized groups globally in the dietary study (mice of oxidized groups vs. mice of unoxidized groups). Differences were considered significant at the $P < 0.05$ level.

RESULTS

Diet compositions and biometric data

Table 2 shows that we succeeded in producing lipid mixtures containing different amounts of oxidation products, especially 4-HHE which was significantly higher in oxidized vs unoxidized lipid blends. MDA and hydroperoxides in oxidized oils were in a reasonable range considered as acceptable for human consumption. Noticeably, oxidation did not impact the fatty acid profile (Table 2); *n*-3 PUFA content and *n*-6/*n*-3 ratio were consistent with dietary recommendations. Mice in oxidized and unoxidized groups did not differ in final body weight gain, liver weight, white adipose tissue, plasma TAG or plasma NEFA (Table 3).

Aldehyde stress and inflammatory markers in plasma of mice fed oxidized *n*-3 diets

Because consuming oxidized *n*-3 diets could contribute to circulating biomarkers of lipid peroxidation such as 4-HHE and 4-HNE, we measured these 4-hydroxy-2-alkenals in plasma. Figure 1A shows a 4-fold increase of 4-HHE concentration in the plasma of oxidized groups (427 to 508 nM) vs non oxidized groups (89 to 128 nM) ($P < 0.01$). However, the concentration of 4-HNE (from *n*-6 PUFA) did not differ among groups (from 6 to 9 nM; Fig. 1B).

FA composition of total plasma lipids was characterized to test whether chronic ingestion of oxidized diet would affect PUFA metabolism. Plasma FA profile (see *Supplemental Table*) actually reflected the composition of ingested dietary fats. The proportions of *n*-3

PUFA (EPA, DHA, alpha-linolenic acid) and *n*-6 PUFA (arachidonic acid, 20:4 *n*-6; linoleic acid, 18:2 *n*-6) were similar in plasma of each oxidized and corresponding unoxidized groups.

Regarding metabolic inflammation, we show higher concentrations in plasma of the pro-inflammatory cytokine IL-6 (Fig. 1C) and of the chemokine MCP-1 (Fig. 1D) in oxidized groups.

Altogether, high-fat diet containing realistically oxidized *n*-3 PUFA induced the highest amounts of 4-HHE and of inflammatory markers in plasma. We therefore questioned whether oxidized oils would affect the small intestine, which is the primary defense line of the host regarding ingested products.

Effects of oxidized diets on markers of stress and inflammation in the small intestine

We analyzed the small intestine mucosa regarding the expression of genes that are known to be specifically involved in cell defense against oxidative stress and detoxification. The expression of mGPx2, a gastrointestinal glutathione peroxidase (GI-GPx) mainly expressed in the intestine, was increased specifically in the jejunum of oxidized groups (Fig. 2D, $P < 0.05$). Moreover, we examined the gene expression of two markers that are linked to endoplasmic reticulum (ER) stress. Mice fed oxidized diets exhibited a significantly higher expression of pro-survival factor glucose-regulated protein 78 (GRP78) both in the duodenum and in the jejunum (Fig. 2B; E, $P < 0.05$). The pro-apoptotic C/EBP homologous protein (CHOP) was significantly higher in the jejunum of oxidized groups (Fig. 2F). However, on the whole down in the ileum, no effects of *n*-3 PUFA oxidation was observed. Regarding inflammation, results show that the jejunum of mice fed oxidized diet exhibited an increased phosphorylation of NF- κ B P65 (Fig. 3A, $P < 0.0001$), a major transcription factor involved in inflammation, associated with a significant increase of

phosphorylated I κ B α , an inhibitor NF- κ B protein (Fig. 3B, $P<0.0001$). The activation of NF- κ B required the phosphorylation and degradation of I κ B protein that prevents the nuclear translocation of active NF- κ B. We also analyzed Paneth cells in the duodenum, which are involved in innate immunity by sensing bacteria and by discharging antimicrobial peptides including α -defensins. Paneth cell number was significantly decreased after oxidized vs unoxidized diets (Fig. 3C). Moreover, the gene expression of Lysozyme 1 produced by Paneth was decreased cells in the duodenum in the PL-ox group compared with PL group (93 ± 20 vs 315 ± 161 ; values normalized to the levels of HPRT mRNA); no differences were observed lower in the intestine in the jejunum ($15-17 \pm 2$ mRNA/HPRT regardless of oxidation) nor in the ileum ($\sim 250 \pm 100$ mRNA/HPRT regardless of oxidation).

Kinetics of intestinal absorption of 4-HHE in mice and protein modifications in the small intestine

To test the hypothesis that the increased plasma level of 4-HHE following consumption of oxidized diet could be partly explained by the absorption of 4-HHE in the small intestine we measured the levels of 4-HHE in the plasma of fasted mice after gavage with 4-HHE. Fig. 4A shows that 4-HHE intragastrically fed to mice at $88 \mu\text{mol/kg b.w.}$ was partly absorbed after 1 h. Peak plasma concentration of 184 nM was reached 2 h after treatment ($P<0.001$ vs. baseline), corresponding to $\sim 0.1\%$ of the fed dose. Importantly, no concomitant differences were observed in the plasma levels of 4-HNE (Fig. 4B).

We further tested the formation of Michael adducts of proteins in the duodenum and jejunum. As shown in Fig. 4C& D, there were significant increases of 4-HHE protein adducts peaked at 2 h postgavage both in the duodenum ($P<0.001$ vs. baseline) and in the jejunum ($P<0.05$ vs. baseline). The observed decrease in adduction at 4 h reveals the

capacity of intestinal mucosa to cope with carbonyl stress. We also observed an activation of GPx2 mRNA in the duodenum 4 h after gavage with 4-HHE: 80 ± 32 vs 38 ± 12 at baseline (mRNA/HPRT, $P=0.013$); this effect was no longer observed in the jejunum (10 ± 3 at 4h vs 9 ± 6 at baseline).

Absorption of 4-hydroxy-2-alkenals in vitro by Caco-2/TC7 cells

In order to further evaluate the capacity of enterocytes to absorb 4-hydroxy-2-alkenals, we incubated Caco-2/TC7 cells for 24 h with increasing concentrations of 4-HHE or 4-HNE. 4-hydroxy-2-alkenals were devoid of cytotoxic effects as checked by the absence of leakage of lactate dehydrogenase and did not alter TEER, meaning that cell monolayer maintained its integrity (data not shown).

Fig. 5 shows that the basolateral medium (BLM) concentration of 4-HHE was significantly increased in a dose-dependent manner from $10 \mu\text{M}$ ($P<0.01$ vs. control). Meanwhile, 4-HNE was increased from $50 \mu\text{M}$ compared with untreated cells. Detected 4-hydroxy-2-alkenals concentrations in BLM corresponded to ~0.2-1% of incubated amount. Noticeably, using similar concentrations, 4-HHE was more abundant in the BLM than HNE ($P<0.0001$).

Protein modifications by 4-hydroxy-2-alkenals in Caco-2/TC7 cells

We quantified protein carbonylation and the formation of aldehyde-protein adducts. Cell incubated for 24 h with increasing concentrations of 4-HHE or 4-HNE exhibited an increased level of reactive carbonyl group in proteins in a dose-dependent manner from $50 \mu\text{M}$ ($P<0.0001$) vs untreated cells (Fig. 6 A,B). Fig. 6C also reveals a significant increase of HNE-protein adducts after incubating cells for 2 h with 4-HNE from $10 \mu\text{M}$ in a dose-

dependent manner vs untreated cells. Similar treatment using 4-HHE resulted in increased amounts of HHE-protein adducts from 50 μ M ($P<0.05$) (Fig. 6D).

GPx2 and ER stress-linked gene expression in Caco-2/TC7 cells

We then sought to determine whether some antioxidant systems were changed due to 4-hydroxy-2-alkenals. Fig. 7 (A, B) shows that mGPx2 expression tended to increase after 24 h at 50 μ M of either 4-HNE or 4-HHE ($P=0.06$) and significantly increased at a concentration of 100 μ M ($P<0.05$) compared with control. Moreover, 4-HNE and 4-HHE (100 μ M) led to increased expression of GRP78 ($P<0.05$) (Fig. 7 C, D).

DISCUSSION

This study is the first to highlight the effects of dietary oxidized *n*-3 PUFA after ingestion on several markers of oxidative stress and inflammation. We tested the hypotheses that a long-term intake of limited amounts of oxidized *n*-3 PUFA, chosen to mimic oxidized *n*-3 levels that can be encountered in foodstuffs, enhances markers of oxidative stress and inflammation in mice, partly due to intestinal absorption of 4-HHE.

We show for the first time that the plasma concentration of 4-HHE, a marker of *n*-3 PUFA lipid peroxidation (23), was increased after chronic intake of oxidized *n*-3 PUFA. In lipid mixtures, the level of 4-HHE was higher in oxidized oils compared to unoxidized oils; We therefore propose the possibility of a partial intestinal absorption of 4-HHE contained in the diet. Results indeed show that gavage with 4-HHE increased transiently the plasma concentration of 4-HHE in mice. The increase of plasma 4-HHE may be attributed to absorption of exogenously fed 4-HHE; while keeping in mind that a deduction on the bioavailability of 4-HHE cannot be made from the present study due to the lack of deeper pharmacokinetic data. *In vitro*, Caco-2 cell study confirms that up to 1% of the amount of

4-HHE incubated can be absorbed despite its high reactivity within cells. Moreover, lower amounts of 4-HNE than 4-HHE were found in BLM suggesting that 4-HNE is less absorbed by the intestine. Of note, 4-HNE is more lipophilic than 4-HHE (23), which could explain its lower absorption and its lower abundance in plasma. A 2.8-fold higher level of plasma 4-HHE was observed in the diet study (TG-ox diet, 8 nmol of 4-HHE ingested per day as measured in lipid mixture) compared with acute gavage (single oral 4-HHE intake, 13.2 nmol). 4-HHE may thus partly accumulate in plasma after long-term dietary intake.

Regarding the clinical relevance of plasma 4-HHE concentrations observed in this study, limited data is available about the concentration of 4-HHE in human blood in relation to diet. Indeed, in healthy men supplemented with gradually increasing doses of DHA up to 1600 mg per day during 8 weeks, a concomitant increase in plasma 4-HHE was observed from 1 ng/mL to 11 ng/mL; i.e., concentrations of ~100 nM at the end of the 8 week dietary period (24). In our study, the animals were fed during 8 weeks with diets enriched in *n*-3 PUFA, resulting in similar plasma 4-HHE concentrations; i.e. ~90 nM in PL group and ~120 nM in TG group. Therefore, the plasma 4-HHE level after feeding unoxidized *n*-3 PUFA containing diets is of a similar order to those reported by Calzada et al. Moreover, they demonstrated that high DHA supplementation (between 800 and 1600 mg/day), causes a significant increase in plasma levels of 4-HHE. This was attributed by the authors to the *in vivo* generation of oxidative stress due to DHA accumulation in the body (24). According to our results, we raise the question of whether this may be due to some degree of DHA oxidation occurring during the preparation and storage of oil capsules. Thus, our new results demonstrates for the first time that intestinal absorption of 4-hydroxy-2-alkenals can occur both *in vivo* and *in vitro* and that moderate and realistic PUFA oxidation can significantly increase the plasma 4-HHE concentration.

Regarding the practical relevance of dietary origin of oxidation products in humans, few studies to date measured the concentrations of 4-hydroxy-2-alkenals in foodstuff. Surh et al. reported that the Korean daily exposure to 4-hydroxy-2-alkenals was 14 nmol/day for 4-HHE and 17 nmol/day for 4-HNE (25). In our study, the quantity of ingested 4-HHE per day as the one measured in lipid mixtures of high-fat diets was in the range 1-8 nmol/day. This is slightly lower than in Surh et al. study (25), nevertheless our experimental conditions were relevant considering realistic food intakes.

Most of the biological effects of 4-hydroxy-2-alkenals are due to their capacity to react with the nucleophilic sites of proteins to form Michael or Schiff base protein adducts (13, 26), which can be implicated in several diseases such as diabetes (27), atherosclerosis (28) and neurodegenerative diseases (14, 16). Here we found that when 4-HHE was orally administrated to mice, it reacted with functional proteins to form adducts in the duodenum and to a lower extent in the jejunum. Our *in vitro* studies confirm this adduction on absorptive cells. Because the implication of the intestinal barrier in the development of metabolic diseases has been recently revealed (29), the metabolic impact of intestinal alterations by dietary oxidation products deserves further exploration.

To date, the link between the quality of dietary PUFA, *n-6 vs n-3*, and inflammation has been largely studied but little is known about the contribution of PUFA oxidation in inflammation. We show here that the oxidized *n-3* PUFA diet induced higher IL-6, MCP-1 in plasma and activation of transcription factor NF- κ B in intestinal mucosa than unoxidized diet. Because the NF- κ B pathway is implicated in the regulation of genes involved in inflammation (30), altogether our results suggest a link between oxidized *n-3* PUFA and metabolic inflammation. Moreover, among cell lineages in the intestine, Paneth cells are involved in innate immune defense and their depletion or a reduced expression of the Paneth cell defensin HD5 and HD6 is reported in several pathologies (31-33).

Importantly, we show for the first time that dietary oxidized lipids induce a decrease in Paneth cell number in the duodenum. This decrease of Lyz-1 expression, marker of Paneth cells, is confined to the duodenum. Our results raise the question of whether this effect could have contributed to the increase of the systemic inflammation.

In the GI tract, a defense system is known to detoxify and degrade lipid peroxidation products (34) and protect against inflammation (35), such as gastrointestinal glutathione peroxidase. Feeding animals with highly oxidized *n*-6 fat was reported to increase the expression of markers of intestine antioxidant defense (36, 37). Here we show a significant increase in GPx2 mRNA after incubation of Caco-2 cells with 4-HHE or 4-HNE, in the jejunum of mice fed moderately oxidized diet and in the duodenum of mice directly force-fed with 4-HHE. Interestingly, in the force-fed mice, GPx2 expression was highest in the intestinal segment presenting the greater amount of protein adducts. Thus, the intake of oxidized PUFA, or some of their components such as 4-hydroxy-2-alkenals, affects the antioxidant defense system. GPx2 appears here to reflect the activation of a metabolic path for detoxifying 4-hydroxy-2-alkenals and adducts, either generated in the gut or introduced *via* the diet.

GRP78 is widely considered as a common regulator/sensor of ER stress. Overexpression of GRP78 is induced by a variety of environmental stress conditions leading to impairment of essential ER functions in order to maintain cell viability against oxidative stress and apoptosis (38). In addition, ER stress induces genes encoding non ER-proteins such as CHOP associated with growth arrest and induction to apoptosis (39). ER stress may also result from protein denaturation due to carbonylation and/or covalent adducts formation with 4-hydroxy-2-alkenals. We demonstrate for the first time the implication of oxidized PUFA or their end-products in ER-stress in the upper GI (duodenum and jejunum) through induction of GRP78 and CHOP expressions. It is important to note that the effects of

oxidized lipids on the stress markers are different along the intestine with a most significant effect in the jejunum regardless of oil type. Further investigations are needed to clarify the possible interactions between inflammation and ER-stress in the different segments of the intestine in response to oxidized lipids. On the other hand, the expression of GRP78 was reported to increase under conditions of chronic inflammation in the intestine including active Crohn's disease and ulcerative colitis (40). In our study, observed up-regulation of GPx2 and GRP78 can be associated with (i) protein adducts and further activation of NF- κ B and (ii) induction of a protective mechanism against oxidative stress and inflammation. The increase of NF- κ B activation is consistent with published data. Indeed, Shkoda et al. demonstrated that the increased level of GRP78 induces the activation of NF- κ B through the phosphorylation of IKK complex in the intestinal epithelial cells (40). Furthermore, Je et al. showed that the activation of NF- κ B by 4-HHE can occur via NIK/IKK and p38 MAPK pathway in the endothelial cells (41).

In the present study, PL-ox lipid blend contained lower detectable amounts of 4-HHE than TG-ox lipid blend. However, both types of oxidized *n*-3 PUFA-containing diets resulted in significant metabolic effects of similar magnitude, especially regarding plasma inflammation and stress markers in the jejunum. This suggests that inflammatory responses are not a simple reflection of the content of *n*-3 PUFA either in the diet or in the plasma, or of the dietary 4-HHE content. We cannot rule out that observed effects can be due to other bioactive species than 4-hydroxy-alkenals. For example, oxidized phospholipids by themselves have been reported to be proinflammatory (42, 43); advanced oxidation protein products could also contribute to observed effects (44, 45).

In conclusion, our study demonstrates in mice that long-term ingestion of oxidized *n*-3 PUFA induces an accumulation of 4-HHE in plasma, which can be partly due to 4-HHE absorption in the small intestine. Furthermore, oxidized *n*-3 PUFA enhance inflammatory

markers in plasma and ER stress in the upper small intestine and reduce Paneth cell number in the duodenum, possibly through the biological reactivity of 4-HHE. GPx2 appears to be required to defend against injury by oxidative stress markers and prevent inflammation in the intestine. The up-regulation of GPx2 and GRP78 can be considered as an attempt to counteract increased inflammation and oxidative stress, noticed by the formation of Michael adducts and reactive carbonyls on intestinal proteins. Altogether, we highlight that the potential harmful effects of dietary oxidized *n*-3 PUFA should be taken into account in several pathologies. Particularly, it appears of utmost importance in medical and nutritional practice to formulate and handle *n*-3 PUFA-rich foods or supplements with care to avoid PUFA oxidation. This can be particularly relevant in patients suffering from acute or chronic diseases, who increase their *n*-3 PUFA intake because of their reported health benefits.

Acknowledgements

Manar Awada acknowledges her PhD grant from ANR. We thank Lucie Ribourg and Michèle Viau for their work on oil mixtures. Patricia Daira is acknowledged for her help with the 4-hydroxy-2-alkenal assay. We thank Jean-Michel Chardigny for his useful discussions. Isabelle Jouanin (Plateforme AXIOM-MetaToul, Toulouse) is acknowledged for her help with the synthesis of internal standards to measure 4-hydroxyl-2-alkenals in fat. Yvonne Masson is acknowledged for revising English language.

(nmol/g of lipid blend)				
4-HHE (oxidation of <i>n</i> -3)	0.5 ±0.1 ^a	1.2 ±0.2 ^b	1.9 ±0.1 ^c	8.5 ±0.5 ^d
4-HNE (oxidation of <i>n</i> -6)	0.2 ±0.1 ^a	0.5 ±0.1 ^a	1.7 ±0.2 ^b	4.4 ±0.5 ^c
MDA	25 ±2.5 ^a	40.0 ±4.0 ^a	5.9 ±1.2 ^b	35 ±14 ^a
Hydroperoxides				
(µmol eq. H ₂ O ₂ /g lipid)	1.6 ±0.9 ^a	1.3 ±0.1 ^a	3.7 ±0.1 ^b	5.8 ±0.1 ^c

^{a,b,c,d} Means in a row superscripted by different letters are significantly different ($P < 0.05$), Data are mean ± SEM for *n*=3. Abbreviations: FA, fatty acids; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids; MDA, malondialdehyde.

Table 3. Morphologic parameters, food intake and plasma lipid concentrations of mice fed oxidized (PL-ox, TG-ox) or unoxidized (PL, TG) *n*-3 diets.

Morphologic parameters	Mice groups according to dietary lipids			
	PL	PL-ox	TG	TG-ox
Biometric data				
Initial Body weight (g)	23.9 ±0.3	24.0 ±0.3	24.5 ±0.3	24.1 ±0.3
Body weight gain (g)	3.1 ±0.1	4.3 ±0.5	3.7 ±0.3	3.0 ±0.5
Energy Intake (kJ/mouse/d)	60.2 ±1.3	62.7 ±0.3	59.8 ±1.3	68.1 ±1.3 ^a
Liver weight (g)	1.21 ±0.04	1.24 ±0.06	1.27 ±0.04	1.28 ±0.05
WAT weight (g)	0.72 ±0.05	0.95 ±0.10	0.93 ±0.11	0.73 ±0.05
Plasma lipids				
Triglycerides (mM)	0.64 ±0.04	0.64 ±0.10	0.57 ±0.04	0.58 ±0.04
NEFA (mM)	0.27 ±0.01	0.32 ±0.02	0.37 ±0.02	0.28 ±0.01

^a *P*<0.05, ANOVA followed by Fisher test for TG-ox vs. TG.

Data are mean ± SEM for *n*=7-9 per group. Abbreviations: WAT, white adipose tissue.
