To the editor:

Zika fever is an *Aedes*-borne disease caused by a flavivirus (*Zika virus*, ZIKV, genus *Flavivirus*). During the past years ZIKV spread in Polynesia, South-America and the Caribbean.¹ Most ZIKV infections are asymptomatic or result in mild febrile disease with rash and conjunctivitis. Attention was recently drawn to non-vector-borne transmission,² including sexual,^{3,4} probable blood-borne⁵ and mother-to-fetus transmission, and to severe forms such as Guillain-Barré syndrome,^{6,7} acute neurological infections^{8,9} and fetal abnormalities¹⁰ (including microcephaly).

Many aspects of Zika fever natural history remain unknown, *e.g.* the proportion of asymptomatic cases and the duration of viremia. Estimating the prevalence of Zika infections is difficult because a large proportion of infected individuals do not seek medical attention and seroprevalence studies are hampered by antigenic cross-reactivity with other flaviviruses, *e.g.* dengue virus.¹¹ Here, we present a study of ZIKV infection in blood donors from Martinique island (French West Indies, Caribbean region), with novel epidemiological, biological and clinical information that refine the picture of Zika fever in adults.

Following the ZIKV outbreak in 2013-2014 in French Polynesia and the evidence that a significant proportion (3%) of donors were viremic,¹² ZIKV has been recognized in Martinique since the end of 2015, leading to implementation by the French Blood Bank of a systematic individual Nucleic Acid Testing (NAT) of blood donations. Virus detection was performed on plasma samples using a semi-automated platform consisting in a Microlab-STARlet® (Hamilton, Switzerland) and the NucleoSpin® 96 Virus Extraction Kit (Macherey-Nagel, Germany) for nucleic acids extraction, and a CFX96 thermocycler (Bio-Rad Laboratories, California) and the RealStar® Zika Virus RT-PCR Kit_1.1 (Altona Diagnostics, Germany) for RT-PCR testing.

Between January-19th and June-10th 2016, 4,129 consecutive blood donations were tested (mean age: 41.9 years; sex ratio (M/F): 0.88). Positive NAT detection occurred in 76 blood donations (1.84%) with the most intense detection rate (3%) during weeks 17-20 (mean age: 41.8 years; sex ratio: 1.2). Post-donation enquiry consisted in a phone call at day 7 post-donation to identify symptoms compatible with ZIKV infection. When the donor declared no sign, a new call was organized 14 days post-donation. This information was obtained from 75 viremic donors: 34 (45.3%) remained asymptomatic; 41 (54.7%) reported symptoms (1-6 days post-

donation, figure 1A) such as fever, conjunctivitis, myalgia, arthralgia and rash (figure 1B). There was a trend for higher values of molecular viral load in symptomatic vs asymptomatic donors: mean values 5.36 vs 4.93 \log_{10} RNA genomic equivalents/mL, Independent Wilcoxon test p-value=0.0013 (figure 1C). This difference does not imply that symptomatic donors reached higher viremia than asymptomatic donors: sampling could occur in the former only during the early steps of viremia, while in the latter, it could also occur during the decreasing phase of viremia. The range of viral loads (2.09-6.50 \log_{10} RNA copies/mL) was comparable to that previously described in French Polynesian asymptomatic blood donors.¹³ Men declared symptoms less frequently than women (45.2% vs 66.7%, Chi² test p-value=0.06) but viral load and time to declaration of symptoms were not significantly different in men and women. No significant association of viremia with ABO, Rhesus and Kell blood groups was detected.

We performed seroprevalence analyses at two time points: in 418 donors sampled in early March (9th-23rd), and in 176 donors sampled in early June (6th-13th). Samples were tested using an anti-Zika virus NS1 IgG ELISA kit (anti-Zika Virus ELISA IgG, Euroimmun, Germany) and positives were further processed by microneutralisation in a 96-well format, using Vero cells, 50 pfu of the MRS_OPY_Martinique_PaRi_2015 strain¹⁴ and a threshold titer of 40 as recommended by the French National Reference Centre for Arboviruses. The seroprevalence after seroneutralisation was 13.5% in early March and 42.2% in early June. An ELISA ratio >4 was associated with a positive seroneutralisation in more than 95% of cases. Sera with an ELISA ratio >5 were associated with seroneutralisation in 100% of cases.

During the same period, the cumulative curve of incident cases detected by NAT in blood donors was almost linear (figure 2A). This allowed performing a simulation analysis and determining, based on the incident cases detected amongst blood donors, the number of donors infected by ZIKV at different time points. Starting from the hypothesis of a random distribution of (i) the first day of detectable viremia in infected donors during all days of the period studied, and (ii) the day of donation during the days open to collection during the same period, we estimated the number of cases for which donation would occur during the phase of asymptomatic viremia detectable by NAT. We deduced the expected prevalence of ZIKV infection in donors for theoretical durations of asymptomatic viremia in plasma of 4 to 6 days (figure 2B), by reference to dengue¹⁵ and chikungunya fever.¹⁶ A faithful correlation with actual seroprevalence results was observed for a duration of asymptomatic viremia of 6 days (prevalence estimated at 12.5% vs 13.5% by seroneutralisation in early March,

and at 43.5% vs 42.2% in early June). This is consistent with the observation that the longest period reported between blood donation and symptoms (pre-symptomatic viremia) was 6 days (figure 1a). Since detection methods using whole blood samples have allowed detecting virus RNA up to 68 days following the onset of symptoms,¹⁷ it will be important to determine if such samples contain infectious virus, and re-assess ZIKV transfusion risk accordingly.

The estimated number of clinically suspect cases in Martinique (French Public Health institute) was ~7,600, *i.e.* ~2% of the population, in early March (week 8) and ~28,900, *i.e.* ~7.6% of the population, in early June (week 22).¹⁸ With reference to seroprevalence results, this suggests that the proportion of cases which did not seek medical attention was 80-85% and did not change significantly along the study period. Our analyses suggest therefore that ZIKV has spread in the general population silently, with a minor impact of the acute disease on medical structures (*e.g.*, 10-35 weekly consultations for Zika syndromes in emergency departments, 10-20 in obstetric departments). The most significant medical impact consisted in 19 Zika-related GBS confirmed cases and Zika infection in 342 pregnant women at the end of our study (June-2016).¹⁹ Therefore the situation is significantly different from that previously observed in Martinique during the 2014 Chikungunya outbreak, characterized by a high proportion of cases seeking medical attention²⁰.

We conclude that ZIKV individual NAT screening in Martinique during 5 months of circulation of the virus allowed the detection of approximately 2% of contaminated blood donations. The proportion of truly asymptomatic cases of Zika disease among Martiniquan blood donors infected by ZIKV was *ca.* 45% and the proportion of cases that did not require medical attention was even higher (80-85%). The duration of plasma asymptomatic and pre-symptomatic viremia was estimated to be close to 6 days. We suggest that, once the duration of asymptomatic viremia has been estimated (*e.g.*, from early analysis of seroprevalence and PCR detection datasets), NAT incidence studies in blood donors could improve prevalence estimates in the general population in the case of a disease with frequent mild or asymptomatic clinical presentations such as Zika fever. The French Blood Bank experience of individual ZIKV NAT screening and epidemiological studies performed from blood donors may be of interest at the time the U.S. Food and Drug Administration is recommending that blood banks screen all blood donations for ZIKV or utilize a FDA approved pathogen reduction technology.

Authorship contributions: P.R. and L.P. collected samples and data from blood donors; A.C. collected and interpreted data from general population. P.G. and P.T. established the RT-PCR platform and performed NAT screening; B.P. and I.L-G. designed and performed serological detection; P.G., P.T., R.N.C. and X.d.L. designed the study, interpreted the data, wrote and edited the manuscript. -PG, AC, RC, BP, ILG and XL are members of the ZIKAlliance project funded by the European Commission.

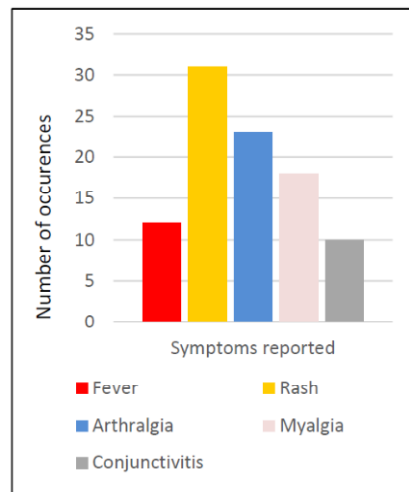

Figure 1. Clinical symptoms and Zika viral loads in blood donors.

The distribution of symptomatic donors according to time of inaugural symptoms (1A) and the frequency of reported symptoms (1B) are presented. Zika viral loads (log₁₀ copies/mL) are provided in both asymptomatic and symptomatic blood donors (1C). Zika viral load was determined by real-time RT-PCR in 41 donors reporting clinical signs and 34 who did not. The diagram reports for each series the quantitative distribution of viral load together with the median value \pm SD.

Figure 2: Epidemiological dynamics of Zika outbreak in Martinique

Figure 2A reports the cumulative incidence of Zika virus NAT detection in blood donors (normalized for 100 weekly blood donations). Figure 2B shows the simulated prevalence of Zika virus infections in blood donors at different time points, based on incident cases and on different hypotheses for the duration of asymptomatic viremia (4-6 days). It also presents the actual seroprevalence data obtained by seroneutralisation at weeks 8 and 22.
