ABSTRACT

Mood depressive disorder is one of the most disabling chronic diseases with a high rate of everyday life disability that affects 350 million people around the world. Recent advances in neuroimaging have reported widespread structural abnormalities, suggesting a dysfunctional frontal-limbic circuit involved in the pathophysiological mechanisms of depression. However, a variety of different white matter regions has been implicated and is sought to suffer from lack of reproducibility of such categorical-based biomarkers. These inconsistent results might be attributed to various factors: actual categorical definition of depression as well as clinical phenotype variability. In this study, we 1/ examined WM changes in a large cohort (114 patients) compared to a healthy control group and 2/ sought to identify specific WM alterations in relation to specific depressive phenotypes such as anhedonia (i.e. lack of pleasure), anxiety and psychomotor retardation —three core symptoms involved in depression. Consistent with previous studies, reduced white matter was observed in the genu of the corpus callosum extending to the inferior fasciculus and posterior thalamic radiation, confirming a frontal-limbic circuit abnormality. Our analysis also reported other patterns of increased fractional anisotropy and axial diffusivity as well as decreased apparent diffusion coefficient and radial diffusivity in the splenium of the corpus callosum and posterior limb of the internal capsule. Moreover, a positive correlation between FA and anhedonia was found in the superior longitudinal fasciculus as well as a negative correlation in the cingulum. Then, the analysis of the anxiety and diffusion metric revealed that increased anxiety was associated with greater FA values in genu and splenium of corpus callosum, anterior corona radiata and posterior thalamic radiation. Finally, the motor retardation analysis showed a correlation between increased Widlöcher depressive retardation scale scores and reduced FA in the body and genu of the corpus callosum, fornix, and superior striatum. Through this twofold approach (categorical and phenotypic), this study has underlined the need to move forward to a symptom-based research area of biomarkers, which help to understand the pathophysiology of mood depressive disorders and to stratify precise phenotypes of depression with targeted therapeutic strategies.

1. Introduction

Mood Depressive Disorder (MDD) is one of the most disabling chronic diseases with a high rate of everyday life incapacity that affects 350 million people around the world (Smith, 2014). This pathology is considered underdiagnosed, without adequate therapeutic resources, which emphasizes the need to be a public health priority (Ferrari et al., 2013). One of the most important causes of misdiagnosis is the poor intrarater reliability of actual classifications (Freedman et al., 2013). Mood Depressive Episode criterion of the Diagnostic and Statistical Manual of Mental Disorders (DSM–5) (Edition, 2013) indeed encompass a wide range of clinical phenotypes of depression “from gravely disabled melancholic patients to many individuals in the general population who do not seek treatment” (Freedman et al., 2013). This suggests that categorical approach provided by DSM-5 is far from the level of neurosciences (Maj, 2014) and therefore could limit reproducibility of its findings in helping in diagnosis and therapies. In this context, despite the extensive therapy options available for depression, up to 80% of patients will suffer from a relapse (Gotlib and Hamilton, 2008). On the neurobiological side, this disease is characterized by a profound

Available online 04 February 2019

and persistent dysregulation of affect and mood (Fitzgerald, 2013), which coexists with additional disturbance including cognitive dysfunction, insomnia, fatigue and appetite disturbance (Drevets, 2001). Consequently, understanding the neural correlates underlying depression, and its phenotype variability, will optimize the diagnosis and treatment of individual depressed patients.

Over the last decades, recent advances in neuroimaging have greatly increased our knowledge of MDD, particularly its neural bases. Widespread structural abnormalities have been reported including regional tissue loss in the hippocampus, amygdala, basal ganglia, prefrontal cortex and anterior cingulate cortex (Arnone et al., 2013; Zou et al., 2010). These results suggested that a dysfunctional cortical-subcortical neural circuit is involved in the pathophysiology and psychopathology of depression (Chen et al., 2016; Korgaonkar et al., 2011; Sacchet et al., 2014). More particularly, an abnormal frontal-temporal network is considered as the locus of the dysfunction underlying mood-regulation in MDD (Chen et al., 2016; Korgaonkar et al., 2011; Sacchet et al., 2014). Structural connectivity analysis provides novel insights into network dysfunctions. White matter (WM) investigations have become a rapidly growing area of research in psychotic disorders including schizophrenia (Buchsbaum et al., 1998), bipolar disorder (Benedetti et al., 2015; Magioncalda et al., 2016) and depression (Chen et al., 2017). In this context, diffusion-weighted imaging (DWI), a noninvasive magnetic resonance imaging (MRI) technique based on the extent of water diffusion, enables the quantification of the fiber orientation and abnormalities of WM pathways within neural networks (Assaf and Pasternak, 2008; Taylor et al., 2004). The most common DWI measure is the fractional anisotropy (FA), an invariant property of DWI that reflects a nonspherical diffusion tensor with a preferential orientation.

Several studies (Chen et al., 2017; Korgaonkar et al., 2011) have revealed significant FA reductions in the body of the corpus callosum (CC) (Han et al., 2014; Korgaonkar et al., 2011), bilateral anterior limb of the internal capsule (ALIC) (Chen et al., 2016; Jia et al., 2018; Zou et al., 2008) and superior longitudinal fasciculus (SLF) (Ota et al., 2015) in MDD patients relative to healthy controls. However, existing knowledge about WM changes is limited due to the variety of different WM regions exhibited in these studies (Liao et al., 2013; Murphy and Frodl, 2011; Sexton et al., 2009). These inconsistent results might be attributed to various factors. The high heterogeneity of MDD individuals in terms of disease characteristics (i.e. symptoms and duration of the disease), could be considered a main cause of this variability (Chen et al., 2016). Previous studies have indeed demonstrated the influence of episodes or illness duration (de Diego-Adelino et al., 2014), illness severity (Henderson et al., 2013) and antidepressant drugs (Dusi et al., 2015; Taylor et al., 2014) on WM. The FA reduction was indeed associated with depression severity and illness duration in MDD patients in the genu of corpus callosum, anterior thalamic radiation, anterior cingulum, and sagittal striatum, which indicates that DWI may be of clinical value in measuring and tracking disability in MDD (Chen et al., 2016; Henderson et al., 2013). One additional source of heterogeneity could be the clinical phenotype (Fried, 2015), such as anhedonia (i.e. lack of pleasure), anxiety and psychomotor retardation—three core symptoms involved in depression. As mentioned above, DSM-5 diagnosis criteria include a wide panel of emotional, motivational and cognitive symptoms (Edition, 2013). Some of these dimensions can be negatively correlated such as motivation and anhedonia severity (Batal et al., 2017). Then, the high variability of diagnosis criteria could lead to poor diagnosis interrater reliability (Friedman et al., 2013). For the last two decades, neuroimaging studies in MDD have identified many putative biomarkers, based on actual disease classification, which remain inconsistent tools. Therefore, there is a need to find new imaging biomarkers which could potentially improve our understanding the pathophysiology of MDD (Young et al., 2016).

In this context of research on biomarkers, the research domain criteria (RDoC) program have been created. This initiative was proposed by the American National Institute of Mental Health to develop “new ways of classifying mental disorder based on behavioral dimensions and neurobiological measures” (NIMH, 2008). This approach promises to increase our understanding of basic network-level abnormalities and their relation to psychopathology (Insel et al., 2010). Then, this new research framework based on dimension could help a better understanding of phenotypic variability described in depression. This disease, as currently defined, spans two of the RDoC domains: the loss construct within the negative valence systems domain and various reward constructs within the positive valence systems domain. Our study focuses specifically on these two dimensions, anxiety and anhedonia by analyzing theirs relations with diffusion metrics (Cutbert and Insel, 2013; Insel et al., 2010). Then, although RDoC program does not propose a behavioral domain, the relationship with psychomotor retardation was investigated because of its central role in depression and discriminative potential for different phenotypes (melancholic subtype, bipolar/unipolar and consequences on treatment) (Bennabi et al., 2013).

In this paper, we proposed a twofold approach (categorical and phenotypical), in order to show that a phenotypic approach allows to identify more reliable knowledge on pathophysiology underlying depression than categorical one. Therefore, the first aim of this study was to examine WM changes in a large cohort of MDD patients to address more consistent and replicable WM microarchitecture abnormalities than those found in previous studies. The second aim of our study was to identify specific WM alterations in relation to specific dimensions of depression such as anhedonia, anxiety and psychomotor retardation.

2. Materials and methods

2.1. Participants

One hundred and fourteen depressed patients were recruited from routine care units in the psychiatric university hospital of Rennes between November 2014 and January 2017 and were enrolled in a naturalistic prospective cohort study. The study was approved by an ethic committee and is registered in www.clinicaltrial.gov (NCT02286024), written informed consents were obtained from all subjects.

The study was proposed to patients suffering from a Mood Depressive Episode (MDE) under DSM-5 criteria with or without personal history of MDD (unipolar or bipolar subtype). Exclusion criteria included other Axis-I disorders (except for obsessive-compulsive disorder and four anxious comorbidities such as posttraumatic stress disorder, social phobia, generalized anxiety disorder or panic disorder), and psychotic symptoms, which were explored using the Mini-International Neuropsychiatric Interview (Lecrubier et al., 1997). Patients with severe chronic physical illness were not included. Other exclusion criteria were potential safety contraindications for MRI (pacemakers, metal implants, pregnancy, and lactation), diagnosed neurodegenerative disorders (e.g. Parkinson’s disease, Alzheimer’s disease, Huntington’s disease), a history of significant head injury, or diagnosed dementia (according to DSM-5 criteria).

Depressed patients underwent clinical interview and examination, including routine neuropsychological testing and MRI. For each subject, demographic data, comorbidities and medication, as well as clinical variables were collected (see Table 1). A composite measure of medication load for each patient was assessed using a previously established method (Sackeim, 2001), taking into account the number of medication class prescribed to the patients as well as each dosage.

The control group was composed of 65 healthy volunteers, who previously participated in neuroimaging studies. The two groups were matched in terms of age (CTL: 48.6 ± 11.8, MDD: 48.3 ± 15.4; Student t-test p-value = 0.5) and gender (CTL: 17M/48F, MDD: 43M/71F; Chi-square p = 0.5).
2.2. Clinical assessment

Patients were assessed by a single structured clinical interview by a trained psychiatrist. Anxious comorbidities were retrieved using the Mini-International Neuropsychiatric Interview (Lecrubier et al., 1997). Depression severity was assessed using Montgomery and Åsberg Depression Rating Scale (MADRS) (Montgomery and Åsberg, 1979). Manic symptoms were retrieved using the Young Mania Rating Scale (YMRS) (Young et al., 1978). Additionally, the Widlöhö Depressive Retardation Scale (WDRS) (Widlöcher, 1983) was used to estimate psychomotor retardation. State anxiety was measured using State-Trait Anxiety Inventory A (STAI-YA) (Spielberger et al., 1970). Then, the anxiety and apathy scores were assessed by Snait Hamilton Pleasure Scale (SHAPS) (Snait et al., 1995) and Apathy Evaluation Scale (YMRS: Young Mania Rating Scale).

2.3. MRI acquisition

Patients and healthy subjects were scanned on a 3 T whole body Siemens MR scanner (Magnetom Verio, Siemens Healthcare, Erlangen, Germany) with a 32-channel head coil. The 3D T1-weighted image was acquired using a linear and non-linear block-matching algorithms (Commowick et al., 2012a; Ourselin et al., 2000). Then, we applied the atlas ImagePreprocessing/animaDiusionImageProcessing.py.

2.5. Statistical analysis

For each diffusion metric map (FA, ADC, AD and RD), independent 2-sample t-tests were also performed on a voxel-by-voxel basis via AFNI’s 3dttest++ (p < 0.001) between MDD and CTL, with age, gender and duration of disease as nuisance covariates. To correct for multiple comparisons, Monte Carlo simulations via AFNI’s 3dClustSim command (Forman et al., 1995) were applied to obtain a corrected significance level of p < 0.05. This correction for multiple comparisons was achieved by setting a minimum cluster size of 214 voxels.

To investigate the relationship between diffusion metrics and clinical variables (WDRS, STAI-YA and SHAPS) in the MDD group, a voxel-wise linear regression model was performed in MDD group. The normality of the clinical variable distribution was before verified using Shapiro-Wilk test. Minimum cluster size after correction for multiple comparisons at p < .05 was achieved by setting a minimum cluster size of 214 voxels.

All results except gender and medications are given as mean, standard deviation (SD) and the range. The percentage of patients having used the prescribed medicines: antidepressant, mood stabilizer, antipsychotic and benzodiazepine as well as the medication load has been reported. The MDD group is divided into unipolar (UP) and bipolar (BP) subtypes. The percentage of patients with anxious comorbidities including posttraumatic stress disorder, social phobia, generalized anxiety disorder and panic disorder has been measured.

WDRS: Widlöhö Depressive Retardation Scale; MADRS: Montgomery-Åsberg Depression Rating Scale; STAI: State-Trait Anxiety Inventory A; SHAPS: Snait Hamilton Pleasure Scale; AES: Apathy Evaluation Scale; YMRS: Young Mania Rating Scale.
3. Results

3.1. Demographics and clinical measures

Demographic and clinical variables of the MDD group is summarized in Table 1. Women, middle-aged predominantly represented the patient population. They have severe characteristics of disease with a long mean duration of illness (range: 25% < 3 years and 17% > 21 years) and episode (range: 50% ≥ 14 episodes). A large majority of patients suffered from recurrent depressive episodes (50% of the patients had more than 3 episodes). Actual depressive episode was moderately intense (MADRS total score = 27.4 ± 5.9). Patients did not show any significant manic symptomatology (YMRS total score = 1.6 ± 1.7). Moreover, 78% of this cohort suffered from high anxiety (36 ≤ STAI-YA ≤ 65) and 27% from very high anxiety higher than 65 as well as high rate of anxious comorbidities. All patients were under treatment (Table 1.). A significant correlation between medication load and disease duration was observed ($r = 0.23$ and $p$-value = 0.0072), in the cohort.

3.2. Whole brain structural alteration data: differences between groups

Compared with CTL, the MDD group had lower FA in the cingulum, the inferior longitudinal fasciculus (ILF), posterior thalamic radiation (PTR), cingulum and the genu of CC (see Fig. 1). However, the MDD group had greater FA in the posterior limb of the internal capsule (PLIC) and splenium of CC. The maximum FA differences in genu of CC and splenium of CC were −33% and +11%, respectively. The identified WM regions and the maximum of the t-values for the clusters (corrected for age, gender and disease duration) are summarized in Table 2 (more detail information is reported in Table A.1 in Appendix A).

For these significant regions, the results of two-sample t-test were also reported in the Table 3 for the other diffusion metrics (ADC, AD and RD). Of the 6 clusters examined, all of them showed significant RD differences after FDR correction, whereas only 3 and 5 regions showed significant differences for ADC and AD, respectively.

3.3. Correlation of structural connectivity and clinical scores

Based on the previous results showing similar spatial distribution for all the diffusion metrics, the correlation analyses were restricted to FA values. Moreover, this metric is more likely to capture microstructure-induced diffusion abnormalities that than ADC, AD and RD (Westin et al., 2002).

Analyses revealed eight clusters, as shown in Table 4 and Fig. 2. As the psychomotor retardation increased (i.e. WRDS values increased), the FA value decreased in the body and the genu of the CC, the superior corona radiata, the superior striatum (see Fig. 2.A.). Additionally, as displayed in Fig. 2.B., a positive correlation was found between the FA values and anxiety, measured by STAI-YA, in the genu and splenium of the CC, anterior corona radiata and posterior thalamic radiation. However, anxiety was negatively correlated with FA values in the body of CC. Similarly, a negatively correlation was found between the FA values and anhedonia with cingulum, genu of CC and posterior thalamic radiation. This pattern may represent decreased myelination (Korgaonkar et al., 2011); however, it could also result from an altered WM microstructure in the affected WM tracts (e.g., axonal degeneration (Bennett et al., 2010)).

The CC is the largest WM pathway providing for information transfer between the two hemispheres. The genu is the most rostral region of the CC connecting between prefrontal brain regions. The most caudal region, the splenium, connects association areas of the parietal and temporal lobes (anterior splenium) and occipital lobes (posterior splenium). In addition, the body is the midsection between the genu and the splenium associating the motor areas (Jiang et al., 2017). In general, the corpus callosum changes structurally throughout life, but most dramatically during childhood and adolescence (Ballmaier et al., 2008). Moreover, patients with disruption in axonal myelinization exhibit executive deficits as well as cognitive dysfunction. Therefore, this tract constitutes key components of the frontotemporal and frontolimbic connections whose dysfunction is thought to underlie many of the emotional, cognitive and behavioral deficits associated with depression (Bracht et al., 2015; Drevets, 2001). However, the splenium is less vulnerable to damage than the genu and body of the CC, which are both late-myelinating (Ballmaier et al., 2008). Moreover, reduced callosal thickness was found in this area only in late-onset depression compared to control, reflecting a more widespread compromise in corticocortical connectivity (Ballmaier et al., 2008).

The cingulum bundle lies within the cingulate gyrus and is an important association pathway linking prefrontal and parahippocampal regions. To date, there is no conclusive evidence for cingulum bundle microstructural alterations in MDD groups. No changes in FA were demonstrated in adults (Carballedo et al., 2012; Zhang et al., 2012). However, reductions of FA in this region were reported in treatment-resistant MDD (de Diego-Adelino et al., 2014). The structural brain...

samples in order to better link behavior and biological measures. This issue has been drawn as a good way to take into account clinical variability in depressive disorder (Olvet et al., 2016).

4.2.1. Anhedonia
Consistent with previous studies, we found decreased FA as anhedonia increased in the cingulum. Indeed, Bracht et al. suggested that this tract could be a biomarker of vulnerability to depression (Bracht et al., 2015). Thus, the FA value in the cingulum bundle was also described negatively correlated with trait anhedonia (Keedwell et al., 2012). In addition, the same abnormality was described in women with a family history of depression (Keedwell et al., 2012), or in first depressed un-medicated patients (Zhang et al., 2012). Altogether, these results suggested that cingulum WM alteration is involved in the pathophysiological mechanism of depression and is probably linked with reward sensitivity dimension.

Increased FA related to increased anhedonia was also found in SLF. Some studies reported the role of this tract in linking aspects of default mode network and cognitive control and its consequence on executive functioning (Jenkins et al., 2016). Moreover, patients suffering from depression could exhibit a deficit in executive functioning and related with a deficit in programing actions relative to hedonic valence. However, based on these arguments, the opposite correlation between FA and SHAPS was found in SLF. This result may represent a compensatory neuroplasticity or selective neurodegeneration mechanism (Jenkins et al., 2016; Mole et al., 2016).

Other significant decreased FA were found associated with decreased anhedonia in PTR. This result echoes the literature that pointed out the involvement of thalamic cortical projections in MDD (Hermesdorf et al., 2017, Korgaonkar et al., 2011). Previous studies have found that such WM alterations were particularly significant in melancholic MDD (Korgaonkar et al., 2011). Our study is the first that links anhedonia and PTR. Moreover, decreased FA was related with increased anhedonia in gCC. The WM abnormalities in this region were linked with the severity of depression (Chen et al., 2016). Our study is the first that links anhedonia and PTR. Moreover, decreased FA was related with increased anhedonia in gCC. The WM abnormalities in this region were linked with the severity of depression (Chen et al., 2016). The strucutral alteration in this area leads to disturbances in cognitive functioning such as memory, executive functions and emotions (Chen et al., 2016). Taken together, our result can lead to the hypothesis that WM alteration in gCC and PTR participates to the severity of depression through one specific phenotype involved in emotion regulation, executive functioning, reward, and decision-making such as anhedonia.

4.2.2. Anxiety
To our knowledge, no study has correlated patient anxiety with white matter diffusion metrics in depressed patients. Most of the studies have chosen a categorical approach in comparing MDD with or without anxious comorbidity (Canu et al., 2015; Delaparte et al., 2017). Despite a large sample, no significant connectivity abnormality has been linked with anxiety (Delaparte et al., 2017).

In this study, the phenotypic analysis of anxiety revealed a
relationship between anxiety and FA values in genu and splenium of CC, ACR and PTR. Kim et al. also reported a positive correlation between anxiety and FA values in these three tracts (Kim et al., 2017). Moreover, a meta-analysis has identified that patients suffering from emotional disorders, such as post-traumatic stress disorders had decreased FA in superior corona radiata and anterior thalamic radiation compared with healthy controls (Jenkins et al., 2016).

4.2.3. Psychomotor retardation

Our phenotypic analysis with motor retardation revealed a correlation between increased WRDS scores and reduced FA in body and genu of CC, superior corona radiata and superior striatum. To date, only two studies had explored the relationship between diffusion metrics and motor retardation in depression, using a behavioral metric called actimetry. First, a positive association was found between activity level and structural alterations of cortico-cortical white matter in motor pathways, such the connection between the rostral anterior cingulate cortex and pre-Supplementary Motor Area (SMA) and between the dorsolateral prefrontal cortex and pre-SMA in MDD (Bracht et al., 2012). The authors attributed this result to a relation between these circuits and movement initiation. Then, the second study has pointed out a negative link between FA and left parahippocampal gyrus (Walther et al., 2012), suggesting a plausible link between cerebral alteration in this region and impaired motor planning. Consistent with these results, we exhibited the implication of parahippocampal gyrus and the cingulate. Furthermore, we found that striatal pathway could also play a role in psychomotor retardation. This circuit was also reported in (Bennabi et al., 2013), showing a link between this behavior impairment and dopamine as well as noradrenergic transmission in basal ganglia such as striatum and caudate nucleus.

To sum up, this phenotypic approach pointed out abnormal structural connectivity that have never been demonstrated in depression. One critical finding concerns anxiety which has been linked with higher connectivity in areas such as corpus callosum, anterior corona radiata and posterior thalamic radiation whereas categorical approach for depression have shown strictly the opposite findings for posterior thalamic radiation and genu of corpus callosum. These results support the stratification of patients suffering from depression according to these core dimensions. The phenotypic approach appeared to be a useful way to complete the categorical approach in a better definition of the variability of different clinical profiles. This study is in line with dimensional approach suggested by Olvet et al. (2016) as it allowed a better understanding of critical mechanism involved in pathophysiology of depression and could help to develop more reliable imaging biomarkers.

5. Limitations

The depression cohort is heterogeneous with regard to demographic and clinical parameters such as age and gender of subjects, age of onset of depression, bipolar disorder, potentially increasing variability. However, the patient heterogeneity is also a strength of this study because it disrupts coincidental associations.

Another investigation will be needed to determine whether diffusion changes are associated with poorer neurocognitive performance. Further studies should include neurocognitive tests in order to refine clinical phenotype such as executive functioning, memory, attention, information processing speed, and emotional patterns, and therefore permit a better accuracy of biomarkers.

The clinical variables, SHAPS, WRDS and STAI-YA, were not reported for the CTL group. Further studies could evaluate their effects on WM organization using a cohort including control subject and patients.

All patients were under psychotropic medication. There is some evidence that psychotropic treatment could lead to decreased FA in schizophrenic patients after medication (Wang et al., 2013). Moreover, in the context of depression, several studies reported that brain changes of white matter are associated with the disease process rather than being effects of medication (Bracht et al., 2015).

In the future, we will extend this work by assessing more robust information of white matter microstructure provided by multi-compartment models and multi-shell diffusion MRI data.

Finally, it is important to note that this study cannot be included in a RDoC program. In fact, it does not strictly emphasize the recommendations such as translational perspective (normal to pathologic, from basic science to behavioral science), or the use of reliable and valid measures of fundamental components (Catheblt and Insel, 2013). Nevertheless, this study addresses the utility of a deconstruction of actual phenotype of depression from a simple disease-based biomarker to a more specific, symptom-based, severity-related, biomarker.

6. Conclusions

Our study aimed to conduct both categorical and dimensional approach in the study of anatomical connectivity biomarkers in MDD.

First, our results highlight the well-known WM abnormalities in a large cohort of currently depressed patients and compared to controls. The frontolimbic disconnection hypothesis has been replicated as well as large decreased connectivity in widespread brain areas (corpus callosum extending to the inferior fasciculus and posterior thalamic radiation). In addition to previous studies with smaller samples, our results reveal other patterns of increased FA in posterior limb of internal capsule and splenium of corpus callosum.

On the other side, the phenotypic approach has identified some specific patterns related to anxiety, anhedonia and psychomotor retardation – three core symptoms of depression. This latter approach highlighted that within a depressive population, there is a wide variability of anatomic connectivity dependent on the severity of each core dimension. This study pointed out that such an approach probably allows more specific and accurate biomarkers than categorical ones, which emphasized widespread abnormalities. Ours brings some evidence for the development of more symptom-based approach within depressed samples.

In the future, a dimensional approach, in addition to the categorical one, could help stratifying different depressive phenotypes, better understanding the pathophysiology characterizing core dimensions, and consequently propose a robust framework for developing targeted therapeutic strategies.

Acknowledgments

MRI data acquisition was supported by the Neurinfo MRI research facility from the University of Rennes I. Neurinfo is granted by the European Union (FEDER), the French State, the Britanny Council, Rennes Metropole, Inria, Inserm and the University Hospital of Rennes. This work has been funded by Institut des Neurosciences Cliniques de Rennes (INCR). The authors thank Mr. Stéphane Brousse and Mr. Jacques Soulabaille for their involvement in the conduct of the study.
