Emerging Concept in DNA Methylation: Role of Transcription Factors in Shaping DNA Methylation Patterns

CLAIRE MARCHAL AND BENOIT MIOTTO*

Université Paris Diderot, Sorbonne Paris Cité, Epigenetics and Cell Fate, Paris, France

DNA methylation in mammals is a key epigenetic modification essential to normal genome regulation and development. DNA methylation patterns are established during early embryonic development, and subsequently maintained during cell divisions. Yet, discrete site-specific *de novo* DNA methylation or DNA demethylation events play a fundamental role in a number of physiological and pathological contexts, leading to critical changes in the transcriptional status of genes such as differentiation, tumor suppressor or imprinted genes. How the DNA methylation machinery targets specific regions of the genome during early embryogenesis and in adult tissues remains poorly understood. Here, we report advances being made in the field with a particular emphasis on the implication of transcription factors in establishing and in editing DNA methylation profiles.

DNA methylation is a well-studied epigenetic modification in mammalian genomes, discovered in 1948. It is involved in a number of essential cellular processes such as transcription regulation, cellular differentiation, cellular identity maintenance, X inactivation, gene imprinting, and the cellular response to environmental changes (Klose and Bird, 2006; Guibert and Weber, 2013; Smith and Meissner, 2013; Subramaniam et al., 2014). DNA methylation has proved to be a dynamic process, requiring continuous regulation and potentially having an important regulatory role for tissue-specific differentiation or cellular signaling. Indeed, the analysis of the distribution of DNA methylation at the genome scale, and nowadays at the single-base resolution, in different physiological and pathological states, unraveled that local changes in DNA methylation contribute to cell-type specific variation in gene expression. Furthermore, aberrant DNA methylation patterns are documented in a number of human diseases from Immunodeficiency, Centromere instability, and Facial anomalies (ICF) syndrome to cancer, and contribute to the onset or development of these diseases (Smith and Meissner, 2013; Weng et al., 2013; Subramaniam et al., 2014). Needless to say, these discoveries also fuel the promising idea that therapeutic strategies targeting DNA methylation can be used in the prevention and the treatment of cancer and other human diseases, including neuro-developmental disorders (Weng et al., 2013; Subramaniam et al., 2014). As an example, antipsychotic drugs clozapine and sulpiride, combined with histone deacetylase inhibitor valproate, have a beneficial action in schizophrenia and bipolar patients, maybe because they revert the aberrant DNA methylation status at GABAergic gene promoters (Dong et al., 2008). In 2004, 5-azacytidine (VidazaTM, Celgene Corporation, Summit, NJ). A drug blocking DNA methylation, received approval by the Food and Drug Administration for the treatment of myelodysplastic syndromes (Kaminskas et al., 2005).

In somatic cells, DNA methylation mostly occurs in the CpG context, and 70–80% of CpGs are methylated in mammalian genomes (Lister et al., 2009; Guibert and Weber, 2013; Ziller et al., 2013). DNA methylation is present in gene bodies, intergenic regions, DNA repeats and endogenous retrotransposons. On the contrary, CpG-rich regions of the genome, called CpG islands, are protected from DNA

methylation and, conversely, they coincide with promoters, replication origins and cis-regulatory transcriptional elements (Lister et al., 2009; Ziller et al., 2013). DNA methylation patterns established during embryonic development are faithfully copied through somatic cell divisions. The ubiquitously expressed DNA methyltransferase DNMT1 is predominantly responsible for copying and maintaining DNA methylation pattern after DNA replication, while the *de novo* DNA methyltransferases DNMT3A and DNMT3B are involved in the establishment of new DNA methylation patterns (Fig. 1) (Okano et al., 1999; Sharif et al., 2007; Subramaniam et al., 2014). While mostly stable it has been soon noticed that in certain developmental processes and human diseases DNA methylation can be, globally or locally, erased (Fig. 1). Two main demethylation pathways have been described over the years. Methyl-CpG can be passively removed by blocking methylation of newly synthesized DNA during DNA replication. The methyl-group can also be enzymatically oxidized by the TET (ten-eleven translocation

Figure 1. Overview of the DNA methylation and demethylation pathway. (A) DNMT1 is responsible for the maintenance of DNA methylation during DNA replication. It recognizes hemi-methylated CpG, thanks to its interaction with co-factor UHRF1, and it adds methylation on the un-methylated strand. Black bubbles: methylated CpG. Empty bubbles: un-methylated CpG. (B) DNMT3A/B are responsible for de novo DNA methylation. They establish new patterns of methylation directly from unmethylated CpG-containing sequences. In the embryo, their activity is modulated by a catalytically inactive family member DNMT3L. (C) Passive demethylation occurs through loss of DNMT1/3 activity in actively dividing cells. Loss can be attributed to post-translational modifications, gene mutations, gene silencing or any other mechanism that will eventually lead to DNMT activity inhibition. (D) Active DNA demethylation is catalyzed by the TET family of enzymes. TET1, 2 and 3 can oxydate 5mC into 5hmC (represented in grey bubbles), and eventually oxydate 5hmC into 5-formyl-cytosine and 5-carboxy-cytosine. None of these bases is recognized by DNMTs causing loss of DNA methylation during DNA replication. In addition, these oxydated bases are recognized by the base-excision repair (BER) pathway and catalytically removed.

methylcytosine dioxygenase) family enzymes to give rise to 5-hydroxy-methyl-CpG (5hmC; and other oxydated bases) and subsequently removed by a base-excision repair (BER) pathway to re-introduce an unmodified cytosine (Kohli and Zhang, 2013). DNA demethylation is essential and it plays a predominant role in resetting gene expression in early embryos, in developing germ cells, and in adult tissues (Guibert and Weber, 2013; Kohli and Zhang, 2013; Weng et al., 2013; Messerschmidt et al., 2014).

Promoter CpG density is central to determining how DNA methylation will affect gene expression. Most high-density CpG promoters (HCP), CpG islands, are unmethylated in all tissues regardless of the level of expression of their associated gene (Lister et al., 2009). Low-density CpG promoters (LCP) are mostly methylated, to different extents, regardless of gene activation or repression. On the contrary, methylation of intermediate CpG-density promoters (ICP) correlates with gene silencing, and these promoters have a greater capacity to acquire lineage-specific DNA methylation patterns. Methylation of HCP promoters, during cell differentiation or tumorigenesis, also directly correlates with gene repression and coincides with the presence of repressive histone marks including histone H3 lysine 9 methylation and histone deacetylation (Fournier et al., 2012). It has been postulated that dedicated proteins might bind selectively, and with high affinity to methylated CpG-rich sequences, and participate in the recruitment of chromatin remodeling repressor complexes to silence target genes (Bartke et al., 2010; Joulie et al., 2010; Fournier et al., 2012; Spruijt et al., 2013). Conversely, active promoters and enhancers acquired chromatin marks, such as histone H3 lysine 4 monomethylation (at enhancers) or trimethylation (at promoters) that prevent the

activity of DNMTs (Thomson et al., 2010; Clouaire et al., 2012; Zhou et al., 2012), hence the unmethylated status of most HCP and ICP promoters in the genome (Fig. 2).

The recent advances in the field had a significant impact on our understanding of the role of DNA methylation in mammals, the enzymatic machineries involved in its regulation and its impact on gene expression in normal and pathological contexts. Yet, how local, sequence-specific, DNA methylation is achieved and remodeled still remains elusive. In the current review, we will focus our discussion on the role of transcription factors and signaling pathways in regulating DNA methylation profiles, and their changes in response to developmental and pathological cues.

DNA Methylation and the Regulation of Tissue-Specific Gene Expression During Cell Differentiation

During development, gene activation and repression are tightly regulated to restrict expression to the correct cell type and correct developmental stage. These regulations are controlled by a complex array of transcription factors, histone modifying enzymes, chromatin remodelers, and DNA methylation. With the advent of genome-wide DNA methylation profiling, a variety of examples have been described over the years showing that DNA methylation is dynamically regulated at tissue-specific promoters and cis-regulatory elements during cell differentiation (Hodges et al., 2011; Lienert et al., 2011; Stadler et al., 2011; Hogart et al., 2012; Feldmann et al., 2013; Oda et al., 2013; Ziller et al., 2013). A detailed analysis of these differentially methylated regions indicates that they are often short regions of DNA and enriched in transcription factor

Figure 2. Summary of the nuclear factors and epigenetic marks involved in the maintenance of DNA methylation status in different regions of the genome. The table recapitulates our current knowledge on transcription factors, chromatin remodelers and histone marks contributing to the establishment of DNA methylation and its erasure. The information is presented according to genomic features, sharing common regulators, such as promoters/enhancers, tumor suppressor genes, germline gene promoters, imprinted regions, DNA repeats, and retroviral elements and peri-centromeric regions.

binding sites compared to the rest of the genome (Hodges et al., 2011; Stadler et al., 2011; Hogart et al., 2012; Oda et al., 2013; Feldmann et al., 2013; Ziller et al., 2013). This recurrent observation obviously pointed to a function of transcription factor binding events in causing these changes in the DNA methylation profile. Yet in most cases the factors essential for these changes remain elusive, and the molecular mechanisms recruiting DNA methylation machineries or enzymatic activity at these promoters (or enhancers) partially understood. While such differentially methylated cis-regulatory regions have been identified during hematopoietic, stem, neuronal, skin, liver or kidney cell differentiation we will restrict our discussion to three different examples that have been deeply characterized: the differentiation of embryonic stem cells into neuronal progenitors, myogenic differentiation, and T cell activation.

Our first example is the role of transcription factor REST in embryonic stem cells. Single-base profiling of DNA methylation in murine embryonic stem cells (ESC) and neural progenitors (NP; derived from these ESCs) show that many discrete regions of the genome either gain or lose DNA methylation. A number of these regions overlap with cis-regulatory regions or enhancers (i.e., intermediate CpG content DNA regions), characterized by the presence of dedicated histone marks (e.g., histone H3 lysine 4 mono-methylation), chromatin regulators (e.g., histone acetylase CBP) and transcription factors (Stadler et al., 2011; Feldmann et al., 2013). Analysis of the binding profile of zinc finger protein REST (RE1-silencing transcription factor, also known as Neural-Restrictive Silencer Factor, NRSF) in ESC showed that REST occupied most of these enhancers, differentially methylated during NP differentiation (Feldmann et al., 2013). Using a transgenic approach it was elegantly demonstrated that inactivation of REST induces de

novo methylation of the DNA sequences normally bound by REST and conversely the expression of REST in the REST-null background is sufficient to restore the unmethylated state of the DNA (Stadler et al., 2011). Thus, REST binding is necessary and sufficient to dictate the un-methylated status of the DNA at a number of enhancers in ESC cells. How REST prevents DNA methylation remains less clear. REST may prevent the binding of DNMTs or the spreading of DNA methylation from neighboring regions. Alternatively, REST may recruit the TET family enzymes or other chromatin remodelling complexes to actively protect the DNA from de novo methylation and counteract DNMTs activities. Intriguingly REST is among the most expressed zinc finger factor in ESCs, and might contribute to their pluripotent status (Singh et al., 2008; Buckley et al., 2009; Jürgensen et al., 2009). Thus one can envision that the downregulation of REST expression noticed at the onset of NP-differentiation will coincide with the hyper-methylation of its targets and will promote a neural progenitor expression program. Conversely we can speculate that NP-specific transcription factors, to be identified, may promote loss of DNA methylation at NP-specific enhancers, establishment of active histone marks and further support differentiation. Analysis of the DNA sequences losing DNA methylation during the differentiation of ESC into NP will help characterize these transcription factors. Importantly, REST does not bind in ESC all sequences gaining DNA methylation during NP differentiation. Additional transcription factors, including CTCF (CCCTC-binding factor), contribute to the shaping of DNA methylation in mouse embryonic stem cells (Stadler et al., 2011; Feldmann et al., 2013; Teif et al., 2014). For instance, a class of CTCF binding sites (outside CpG islands) gain DNA methylation and acquire a condensed chromatin structure,

concomitant with CTCF expression down-regulation during NP differentiation (Stadler et al., 2011; Teif et al., 2014).

Our second example is the transcriptional regulation of Myogenin, a muscle-specific transcription factor that determines commitment and differentiation of myoblasts into myotubes. The methylation of the promoter of Myogenin (an intermediate CpG content promoter, ICP) substantially decreases during the process of somitogenesis (Palacios et al., 2010). This phenomenon is recapitulated in an *in vitro* model of muscle cell differentiation (Luo et al., 2009; Palacios et al., 2010; Oikawa et al., 2011). Using this latter model for functional studies it has been shown that the Myogenin promoter is initially methylated and bound by two methyl-CpG binding proteins, ZBTB38 (zinc finger and BTB domain containing 38) and MBD2 (methyl-CpG-binding domain protein 2). At the onset of differentiation, the methylation of the promoter is reduced coincident with Myogenin increased expression. Concomitantly, ZBTB38 protein is degraded by a proteasome-dependent pathway and MBD2 binding is inhibited by a focal adhesion kinase (FAK)-dependent phosphorylation event (Luo et al., 2009; Oikawa et al., 2011). Intriguingly, FAK enhances the transcriptional activity of myocyte enhancer factor 2 (MEF2) and binding of MEF2 to the Myogenin promoter is required for demethylation of the promoter, establishment of active histone marks and gene expression during muscle cell differentiation (Palacios et al., 2010). It is therefore appealing to speculate that induction of FAK activity at the onset of myotube differentiation may regulate a critical switch in sequence-specific transcription factors present at the Myogenin promoter, coincident with demethylation of the promoter, induction of gene expression, and irreversible commitment into the muscle cell lineage. How DNA demethylation is achieved, and its extent, on the other hand has not been properly studied. Whether it is a passive or an active phenomenon also needs to be elucidated.

The third example is the activation of interleukin (IL)-2 gene expression upon activation of naive CD4 T cells (by anti-CD3 ϵ and anti-CD28). In turn IL-2 drives their proliferation. The activation of IL-2 expression coincides with the demethylation of specific CpGs in the promoter of the gene (Bruniquel and Schwartz, 2003). The study of the kinetic of DNA demethylation showed that it occurs in absence of DNA replication indicating an active, enzymatic, mechanism (Bruniquel and Schwartz, 2003). The demethylation of the promoter is not sufficient to activate IL-2 expression and specific transcription factors including NF-AT (nuclear factor of activated T cells) and OCT-1 (octamer-binding transcription factor 1) need to bind to the unmethylated promoter in order to transcribe the gene (Murayama et al., 2006). For instance, in resting cells (after antigen withdrawal) the promoter is in an un-methylated state, bound by OCT-1, but IL-2 is not expressed. On the contrary, after re-stimulation with antigen, IL-2 expression is induced and the transcriptional activation of IL-2 is much faster than in naive cells, suggesting that the absence of methylation on the IL-2 promoter and OCT-1 binding may prime gene expression (Murayama et al., 2006). These data imply that IL-2 expression required demethylation of the promoter upon antigen activation but also binding of a dedicated set of transcription factors. *In vitro* assays and preliminary data *in vivo* suggest that active DNA demethylation may be controlled by DNA glycosylase Myh (MUTYH in human) that is strongly transcriptionally induced upon activation of naive T cells (Wu and Zheng, 2014). Using a very similar method, it was also reported that IL-4 expression is strongly enhanced upon CD4 T cells activation into Th2 cells. Activation of IL-4 is dependent on GATA-3 accumulation, passive demethylation of the locus and release of the methyl-CpG binding protein MBD2 and DNA methyltransferase DNMT1 from the locus (Hutchins et al., 2002; Makar et al., 2003).

Cell fate decisions require (at least) temporal co-expression of tissue-specific genes and environmental stimulation. This regulation primarily orchestrates a switch in the transcriptional program and it is likely that transcription factors, by recruiting DNMTs or demethylating activities, may ensure that tissue-specific gene expression and cell identity are stably maintained during later cell divisions. Consistent with such an interpretation, tissue-specific genes are associated with intermediate CpG-content promoters (ICP), whose level of methylation is strongly correlated with their level of expression (Lister et al., 2009; Joulie et al., 2010; Fournier et al., 2012; Ziller et al., 2013). The variety of tissue-specific genes, hence promoter sequences, on the other hand, suggests that many transcription factors might be required to properly establish tissue-specific DNA methylation profiles. Accordingly, using a protein array analysis Pierre-François Cartron and colleagues have identified a large variety of transcription factors that can interact with DNMTs, and thus probably alter DNA methylation at target genes upon cell differentiation (Pacaud et al., 2014) (Fig. 2).

DNA Methylation and the Silencing of Germline Genes in Somatic Tissues

Germline genes are normally only expressed in germ cells. The regulation of their expression represents a unique example of regulation that primarily relies on DNA methylation. Studies have shown that, in germ cells, CpG-island promoters at germline genes are unmethylated and associated with a chromatin structure characteristic of active gene expression. On the contrary, in somatic tissues, promoters at germline genes are fully methylated and the genes transcriptionally silenced (De Smet and Loriot, 2013). Intriguingly, global hypomethylation in cancer lead to the recurrent activation of a limited number of genes, most of them germline genes. Germline genes are therefore often used as tumor-specific antigens for diagnostic applications and for translational applications. Yet, very little is known on the mechanisms involved in the deposition and maintenance of DNA methylation at these peculiar CpG-island promoters.

An elegant study, by Claire Francastel's laboratory, showed that DNA methylation at several germline genes is altered in a mouse hypomorphic Dnmt3b background and in a null background for transcription factor E2F6. Complementary experiments demonstrated that the protein E2F6 is required for Dnmt3b binding at these germline gene CpG-island promoters in somatic tissues (Velasco et al., 2010). Intriguingly, follow up studies showed that E2F6 interacts with DNMT3B (Pacaud et al., 2014) and that E2F6-binding elements, predicted *in silico*, are detected at germline gene promoters (Borgel et al., 2010). Yet it remains to be formally shown that this interaction leads to the establishment or to the maintenance of DNA methylation. In addition, many E2F6 targets have been described in mouse and human cell lines and most of them are not regulated by DNA methylation (Project Consortium., 2012). It is therefore likely that additional transcription factors help target Dnmt3b at these promoters or that a dedicated E2F6 complex, to be characterized, bind at these promoters together with Dnmt3b (Fig. 2). A good candidate is the cMyc partner, Max (Maeda et al., 2013). Its inactivation in mouse embryonic stem cells causes the reactivation of some germline genes, among other genes (Maeda et al., 2013).

DNA Methylation and the Regulation of Mono-Allelic Expression

DNA methylation plays an essential role in genomic imprinting or mono-allelic expression, the process that causes genes to be expressed only from one parental allele (Hanna and Kelsey,

2014). Over a hundred imprinted genes have been identified and many of these genes are organized in clusters controlled by the differential allelic DNA methylation of a CpG-rich sequence called the imprinting control region (ICR). These regions acquire a parental origin-specific differential methylation in the male or female germline, escape a genome-wide wave of methylation reprogramming during the first days of embryonic development and retain parent-of-origin DNA methylation in the adult. Mono-allelic expression is essential for normal growth and development. Disruption of imprinting may lead to serious developmental disorders (e.g., Prader-Willi syndrome, Angelman syndrome, Beckwith-Wiedemann syndrome) and is described in cancer (e.g., Wilm's tumor) (Lim and Maher, 2010; Hanna and Kelsey, 2014).

Among the factors involved in imprinting, the zinc finger transcription factor Zfp57 is responsible for the maintenance of DNA methylation imprints (Fig. 2). Inactivation of the maternal and zygotic Zfp57 in the mouse results in the loss of differential DNA methylation and genomic imprints (Li et al., 2008). Zfp57 encodes a Kruppel-associated box-containing zinc-finger protein (KRAB-ZNF) factor. Previous studies indicated that the KRAB domain interacts with corepressor protein KAP1 (also known as TRIM28 and TIF1 β), a docking protein for heterochromatin protein 1, histone H3 lysine 9 methylases, and DNA methyltransferases (Quenneville et al., 2012). A molecular analysis of Zfp57 function in embryonic stem cells indicated that the protein binds to the methylated allele of ICRs and recruits KAP1 and associated co-factors onto the methylated allele. Inactivation of Zfp57 in ESC alters DNA methylation, chromatin marks and allelic expression at a number of imprinted regions (Quenneville et al., 2011). Intriguingly, human ZFP57 functionally replaces mouse Zfp57 in embryonic stem cells and mutation in human ZFP57 affect DNA methylation at a subset of imprinted loci in individuals suffering transient neonatal diabetes (Mackay et al., 2008; Takikawa et al., 2013). Altogether these studies suggested a conserved role for Zfp57 in the maintenance of DNA methylation pattern at imprinted loci in mammals, despite clear differences in early embryonic developmental processes.

A genome-wide analysis of Zfp57 targets in ESC indicated that Zfp57 is not selectively binding to ICR regions in the genome (Quenneville et al., 2011). Nevertheless, it binds together with KAP1 and the histone H3 lysine 9 methylase SETDB1 only to these ICR regions, suggesting that a dedicated Zfp57/KAP1/SETDB1 complex ensures imprinting in mouse ESC cells. Analysis of these DNA sequences highlighted the presence of a common methylated hexameric TGC^mCGC sequence motif (Quenneville et al., 2011). In vitro Zfp57 binds to this methylated motif with stronger affinity than the unmethylated counterpart DNA. This latter result strongly supported the role of Zfp57 in targeting the methylated parental allele in vivo to maintain parent-of-origin methylation and expression. How Zfp57 DNA selectivity is achieved is still unclear. Studies will be necessary to understand why the corepressors KAP1 and SETDB1 only stably interact with Zfp57 at these imprinted regions.

Targeting of the KRAB domain alone is sufficient to induce transcriptional silencing and DNA methylation at the targeted locus, even after removal of the transcriptional repressor, in embryonic stem cells (Quenneville et al., 2012). This effect however is not observed in adult differentiated cells where KRAB-mediated gene silencing is not associated with DNA methylation (Quenneville et al., 2012). Thus, thanks to its ability to bind an ICR-specific methylated-sequence and to attract the KAP1/SETDB1/DNMTs complex, Zfp57 is key in the establishment and/or maintenance of DNA methylation pattern at many imprinted loci, in a timely manner, during early mouse embryonic development. Importantly, during development, the other parental allele should remain

unmethylated to perpetuate the differential methylation at ICRs. It is noteworthy to mention that this phenomenon might actually be the result of an active protection mechanism involving transcription factors, chromatin remodelling activities and TET activities.

Zfp57 is only expressed in embryonic stem cells suggesting that other KRAB-ZNF factors (over 400 in the human genome) might be involved in the maintenance of DNA methylation during later developmental stages and in tissues in which Zfp57 is not expressed. Consequently, another KRAB-ZNF factor, ZNF274, emerged as a regulator of parent-of-origin expression. SNORD116, a non-coding RNA contained in the bi-partite Prader-Willi syndrome imprinting center on chromosome 15 in human, is mono-allelically expressed (Cruvinel et al., 2014). Chromatin immunoprecipitation analysis showed that ZNF274 binds specifically to the methylated maternal allele of the ICR in the SNORD116 locus. ZNF274 interacts with KAP1 and SETDB1, and these latter factors are recruited to the ZNF274-bound DNA at the SNORD116 locus (Cruvinel et al., 2014). Yet, ZNF274 also binds to other genomic sites in the human genome that are not subjected to imprinting, and these sites also show significant levels of KAP1 and SETDB1 (Frietze et al., 2010). It thus remains to be properly shown that ZNF274 dictates DNA methylation at the SNORD116 ICR and elucidate how ZNF274 recognizes the ICR. In conclusion, the data still remain sparse to clearly state on the role of ZNF274 in the control of imprinting but, owing to the presence of the KRAB domain and the resemblance with the molecular function of ZFP57, one can suggest a probable similar function.

Other transcription factors have been described to bind to ICRs. Their functions in the control of imprinting and in the establishment or maintenance of the methylation pattern at these ICRs await further investigation. For instance, chromatin immunoprecipitation analysis in chimeric mice indicates that ZBTB38 and ZBTB4 bind to the methylated allele of the Insulin-Like Growth Factor 2 (IGF2) ICR, a growth-promoting hormone during gestation (Filion et al., 2006). Intriguingly, different single-nucleotide polymorphisms in the ZBTB38 locus, correlated with changes in ZBTB38 expression, have been linked to human height phenotype (Gudbjartsson et al., 2008). The ZBTB38 gene, like IGF2, may thus be involved in determining growth, and ZBTB38 might do so by regulating IGF2 mono-allelic expression.

DNA Methylation and the Silencing of Repetitive Elements and Endogenous Retroviral Elements

It is well recognized that DNA methylation represents the primary mechanism of transposition repression in the host genome. In the absence of DNA methylation, DNA repeats and endogenous retroviral elements are re-activated and they invade the host genome leading to a toxic cellular response (Goff, 2009; Rowe et al., 2010; Tan et al., 2013; Wolf and Rowe et al., 2013). Yet, how this methylation is deposited on newly integrated transposable elements and how it is maintained in subsequent cell divisions remains a matter of debate.

A very elegant series of experiments from Didier Trono's laboratory indicated that this regulation might primarily rely on the co-repressor KAP1. The study of gene expression regulation in mouse (tissues and embryonic stem cells) and in human samples inactivated for KAP1 showed a strong reactivation of multiple DNA repeats, notably endogenous retroviral elements (Rowe et al., 2010, 2013; Lukic et al., 2014; Turelli et al., 2014). In addition, analysis of KAP1 binding in ESC cells showed an enrichment at a number of endogenous retroviral elements and mutation of KAP1-residues involved in KRAB-domain binding abolished this binding preference (Lukic et al., 2014). The concomitant identification of the role of KRAB-ZNF

factors in de novo methylation and the rapid expansion of this family of ZNFs in mammalian genomes, led to the hypothesis that KRAB-ZNF factors might rapidly evolve to provide a repertoire of KAP1-interacting DNA binding proteins and counteract accumulation in the genome of foreign transposable elements (Lukic et al., 2014). Consistent with this provocative hypothesis inactivation of at least two different KRAB-ZNF factors causes the reactivation of different classes of DNA repeats in human and mouse cells (Li et al., 2008; Wolf and Goff, 2009; Tan et al., 2013).

Embryonic stem cells have been shown to block retrovirus replication. For example, infection of stem cells by the murine leukemia virus results in its integration in the genome but the retrovirus is then transcriptionally silenced. This phenomenon required specific cis-regulatory element in the viral genome and the recruitment of the KAP1 corepressor (Wolf and Goff, 2007, 2009). A proteomic screen, identified two KRAB-ZNF proteins, ZFP124 and ZFP809, bound onto the viral DNA but only ZFP809 could specifically bind, on its own, to the sequence in vitro (Wolf and Goff, 2009). Functional analyses in ESC cells next showed the key function of ZFP809 in recruiting the KAP1/DNMTs complex to silence the murine leukemia virus (Wolf and Goff, 2009). In another study, inactivation of Zfp819 in mouse embryonic stem cells causes the reactivation of certain endogenous retroviral elements (Tan et al., 2013).

Integration of gene expression profiling and histone marks and transcription factors mapping provided strong evidence that repeated DNA sequences are important regulatory elements in genomes (ENCODE Project Consortium., 2012). As such, they can serve as alternative promoter of genes, enhancers or insulators, among other things. It is thus likely that silencing of these DNA repeats is achieved by, redundant, alternative chromatin remodelling complexes and pathways. Consequently, many functional binding sites for transcription factors, including NFY (nuclear transcription factor Y), STAT1 (signal transducer and activator of transcription 1) and CTCF, are experimentally identified in these repeated DNAs [Project Consortium., 2012]. Yet, in most cases the studies focus on the role of these transcription factors in altering the epigenetic signature or expression level of neighboring host genes. It thus remains to be investigated whether these transcription factors also play a role in the control of repeated DNA silencing and DNA methylation (Fig. 2).

For instance, PLZF (promyelocytic leukaemia zinc finger protein, also known as ZBTB16) plays a key role in the maintenance of germ cells in adult tissue and hematopoietic stem cells (Puszyk et al., 2013). An analysis of DNA methylation profile in bone marrow and testis of mice bearing a DNA-binding inactivating mutation in PLZF identify a hundred of regions differentially methylated, most of them overlapping with a LINE1 (L1) retrotransposon (Puszyk et al., 2013). ZBTB16 targets these L1 elements by interacting both with the DNA and the L1 RNA, leading to the recruitment of DNMT1 and silencing of L1 retro-transposition (Puszyk et al., 2013). Intriguingly, retinoblastoma protein (Rb) also represses L1 elements and it was previously shown that it interacts with ZBTB16 (Petrie et al., 2008). ZBTB16 regulates the expression of both protein-coding genes and DNA repeats. The implication of Rb in both functions highlighted the implication of a common regulatory complex. It also emphasizes that the implication of transcription factors in DNA repeats silencing might have been previously overlooked.

Inhibition of DNMT3A phosphorylation also causes the reactivation of many DNA repeats, independently of DNMT1 and DNMT3B. DNMT3A is a bona-fide substrate for the protein kinase CK2 (Deplus et al., 2014). CK2 phosphorylates DNMT3A at serines 386 and 389 in vivo and in vitro (number according to the mouse protein). Surprisingly this

phosphorylation reduces the de novo methylase activity of DNMT3A in vitro. Yet, in vivo the effects on DNA methylation are context specific, as shown in human cancer cells inactivated for CK2. In unique portions of the human genome no significant change in DNA methylation are detected, while at a subset of DNA repeats both significant hypermethylation (e.g., Alu elements) and hypomethylation (e.g., LINE, LTR, and Satellite repeats) is observed. At the molecular level the phosphorylation of DNMT3A by CK2 controls its subnuclear distribution. Phosphorylated DNMT3A is mostly detected in heterochromatin domains, while dampening the phosphorylation relocates DNMT3A in the euchromatic compartment of the nucleus. Whether the phosphorylation affects the binding of DNMT3A to specific heterochromatic proteins or transcription factors binding satellite DNAs is an exciting hypothesis that will require further investigation.

DNA Methylation and the Silencing of Tumor Suppressor Genes in Cancer

In cancer, a global hypo-methylation of the genome coincides with the development of the disease (Zane et al., 2014). Conversely several CpG islands, including those linked to cancer specific genes affecting cellular growth control, gain methylation and they are stably silenced (Gazin et al., 2007; Thillainadesan et al., 2012; Wajapeyee et al., 2013; Serra et al., 2014). It was thought that the process may be stochastic and that errors in the fidelity of the DNA methylation machinery would randomly cause hyper-methylation of a CpG island of a cancer gene. An alternative model, that regain interest, postulate that oncogenic signaling drives this epigenetic repression in cancer by regulating the function of transcription factors able to attract DNMTs to a CpG island of a cancer gene (Fig. 2).

Using an in vitro system recapitulating the hyper-methylation and silencing of the *Fas* gene by oncogenic Ras (*Kras*), Michael Green's laboratory performed a genetic screen to identify the cellular components required for the silencing of *Fas* (Gazin et al., 2007). They identified 28 factors involved in the process including: the maintenance methyltransferase DNMT1, a serine-threonine kinase PDPK1, different chromatin remodelers (RCOR2, ASF1A, TRIM66/TIF1D, DOT1L, EZH2, SMYD1 and others) and several sequence-specific transcription factors (ZFP354B, ZCCHC4, and SOX14). Using chromatin immunoprecipitation assays they confirmed the direct binding of these transcription factors and chromatin remodelers at the *Fas* promoter in response to expression of activated Ras. Individual inactivation of several of these 28 genes impairs the binding of DNMT1 at the *Fas* promoter and the hyper-methylation of the promoter in response to expression of activated Ras (Gazin et al., 2007). In a follow-up study, the same group studied the hierarchy of these 28 factors. They provided strong evidence that the binding of KRAB-ZNF ZFP354B at the *Fas* promoter is the key event leading to further assemble of transcriptional co-repressors and chromatin modifying enzymes and eventually DNMT1 to the promoter (Wajapeyee et al., 2013). An analysis of additional cancer genes (*Sfrp1*, *Par4*, *Plagl1*, *H2-K1*, and *Lox*) indicates that several of the 28 genes are also required for the silencing of these five genes upon expression of activated Ras (Gazin et al., 2007). At least in the case of *Sfrp1*, ZFP354B binding also preceded co-repressors, chromatin-modifying enzymes and DNMT1 binding (Wajapeyee et al., 2013). Thus activated *Kras* may direct epigenetic silencing at a number of cancer gene relying on the binding of ZFP354B at their promoters.

Using a similar approach, the same laboratory also investigated the hyper-methylation and silencing of the tumor suppressor genes p14^{ARF} in colorectal cancer (Serra et al., 2014). They identified eight genes essential for the transcriptional repression of p14^{ARF} in DLD1 human colorectal

cancer cells that contain an activated KRAS mutation. Among the proteins they identified is the KRAB-ZNF ZNF304 factor. Using a variety of assays, they demonstrated that ZNF304 binds to the p14^{ARF} promoter in different colorectal cancer cell lines and also KRAS-positive human colorectal tumor samples. Inactivation of ZNF304 causes the re-activation of p14^{ARF} expression and the demethylation of the promoter. Surprisingly, other tumor suppressor genes, including p16^{INK4B} (CDKN2B) and p15^{INK4A} (CDKN2A) are also epigenetically silenced by ZNF304 in colorectal cancer cells containing an activated Ras mutation.

Together, these studies indicate that activation of Ras perturbs intracellular signaling leading to the accumulation of KRAB-ZNF factors ZFP354B and ZNF304 in a cancer specific fashion. In turn, these KRAB-ZNF factors specifically bind to unmethylated CpG-rich islands to initiate the recruitment of co-repressors, chromatin remodelers and DNMT1. ZFP354B accumulates in cancer cells because of its transcriptional upregulation and its phosphorylation by Ras-activated kinase PDKPI (Gazin et al., 2007). ZNF304 accumulation in CRC is caused by Ras-induced inactivation of deubiquitinase USP28 (Serra et al., 2014).

Tumor suppressor gene p15^{INK4A} is hypermethylated and silenced in breast cancer. Using MCF7 breast cancer cells, it was demonstrated that hypermethylation of the p15^{INK4A} promoter is dependent on the zinc finger protein ZNF217 (Thillainadesan et al., 2012). ZNF217 overexpression has been observed in many cancer types, including breast cancer, and it is often linked to immortalization, increased proliferation, and resistance to TGF-beta, a cytokine that trigger a complex antiproliferative cellular response. In MCF7 cells, ZNF217 is responsible for the targeting of the co-repressor complex coREST and DNMT3A to the p15^{INK4A} promoter, its hypermethylation and its silencing (Thillainadesan et al., 2012). Surprisingly, the antiproliferative action of TGF-beta involved the demethylation of the p15^{INK4A} promoter and the reactivation of the gene. Study of this mechanisms in MCF7 cells indicate that TGF-beta causes the disassembly of the ZNF217/coREST/DNMT3A complex from the p15^{INK4A} promoter in a few minutes and the concomitant recruitment of transcription factor SMADs, of co-activators CBP and of BER pathway factors AID (activation-induced deaminase) and TDG (thymidine DNA glycosylase) (Thillainadesan et al., 2012).

Epigenetic silencing in cancer also involves non-ZNF transcription factors. Methylation and silencing of tumor suppressor gene RASSF1 is dependent on cMYC and Polycomb-repressor proteins (Palakurthy et al., 2009). Intriguingly, DNMT3B physically interacts with PcG-proteins and with cMYC in the nucleus (Viré et al., 2006). In acute promyelocytic leukemia the oncogenic fusion transcription factor PML-RAR binds the retinoic acid receptor beta-2 promoter and induces its transcriptional silencing, through recruitment of DNMT3A and de novo methylation of the promoter (Di Croce et al., 2002). Again, multiple transcription factors, some of them myc-regulated or mutated in cancer, interact with DNMTs in vitro, and may contribute to aberrant changes in DNA methylation in cancer (Pacaud et al., 2014) (Fig. 2). A key question remaining is to understand how the deregulation (or mutation) of these transcription factors can cause very selective changes in the DNA methylation profile that will promote tumorigenesis. Is this information embedded in the promoter sequence of tumour suppressor genes?

Perspectives in the Field of DNA Methylation

Many transcription factors have been shown to control DNA methylation status of their target sites. Among them, many belongs to the KRAB-ZNF family (Gazin et al., 2007; Li et al., 2008; Wolf and Goff, 2009; Oikawa et al., 2011; Feldmann et al.,

2013; Puszyk et al., 2013; Wajapeyee et al., 2013; Cruvinel et al., 2014; Serra et al., 2014). This later observation may relate to the observation that the isolated KRAB domain by associating with KAP1/DNMTs lead to de novo methylation at target sites in stem cells (Quenneville et al., 2012). It was therefore postulated, and later strongly experimentally supported, that KAP1/DNMTs control the maintenance of DNA methylation, independently of DNA replication, on a number of genomic targets. Yet, DNMTs have been shown to be recruited onto the chromatin by other chromatin remodelers, such as SETDB1 or G9a, or secondary to gene silencing (Gibbons et al., 2000; Dennis et al., 2001; Guibert and Weber, 2013; Pacaud et al., 2014). Thus, only the identification of the full-spectrum of transcription factors involved in the regulation of DNA methylation will tell whether this function is predominantly confer to KRAB-ZNF factors. This systematic analysis might help understand why only a limited number of factors per family are involved in the shaping of DNA methylation. In the case of ZNF factors several explanations have been postulated. The resolution of the structure of the ZNF fingers of Zfp57 bound onto methylated DNA indicated that a specific amino-acid sequence in the DNA binding ZNF fingers might be required for the recognition and binding of methylated CpG sequences (Liu et al., 2012; Buck-Koehntop and Defossez, 2013). Using this knowledge, researchers have postulated that ZNF factors containing this motif might likely contribute to shape DNA methylation profile (Liu et al., 2013). An alternative hypothesis rely on the observation that KRAB-ZNF factors are present uniquely in vertebrate genomes and have expanded quite dramatically in mammalian genomes. As DNA repeats sequences also quickly evolved in mammalian genomes, it is suggested that human-specific KRAB-ZNF factors might primarily contribute in DNA repeats silencing (Lukic et al., 2014).

Another open question, despite intense scrutiny, is the nature of the factors involved in the establishment of DNA methylation at centromeres and telomeres. We still do not know how the DNMTs are targeted to these regions of the genome. Demethylation of pericentromeric satellite type II and III repeats, caused by loss-of-function mutations in DNMT3B, is an important feature of the chromatin in Immunodeficiency, Centromere instability and Facial anomalies (ICF) syndrome patients (Nitta et al., 2013; Weng et al., 2013). Lessons from genetic studies of the causes of ICF indicate that around 50–60% of cases are explained by inactivating mutations in DNMT3B coding sequence. Yet, in the remaining patients no mutation was identified in the coding sequence of DNMT3B. The advent of exome sequencing technologies lead to the identification of mutations in a ZNF factor ZBTB24 in a category of ICF patients (Nitta et al., 2013). In mouse cells, ectopically expressed ZBTB24 and DNMT3B are targeted to pericentromeric heterochromatin compartments, independent of the DNA methylation status (Nitta et al., 2013). Some of the mutations, identified in ICF patients, lies in a well-conserved zinc finger of ZBTB24 and impair the recruitment of ZBTB24 onto pericentromeric DNA in mice cells (Nitta et al., 2013). It is therefore very tempting to speculate that ZBTB24 is responsible for the recruitment of DNMT3B at pericentromeric DNAs and the establishment and/or maintenance of their methylation status. Two helicases, ATRX (alpha thalassemia/mental retardation syndrome X-linked) and Lsh (Lymphoid-specific helicase; HELLS in human), are critically required for the maintenance of DNA methylation at pericentromeric regions in mouse cells (Gibbons et al., 2000; Dennis et al., 2001). These helicases lack a dedicated DNA binding domain and their recruitment at pericentromeric DNA has remained elusive for years. It would be tempting to speculate that ZBTB24 might contribute to target these helicases. Further studies will be required to clarify ZBTB24 function at centromeres.

Local changes in DNA methylation have been noticed in other context than cancer. For instance, neuronal activity induces local and specific changes in DNA methylation in the brain (Martinowich et al., 2003; Murgatroyd et al., 2009). Aberrant DNA methylation has been described in patients subject to a number of psychotic and neurodevelopmental disorders, including alzheimer disease, schizophrenia, anxiety, and cognitive deficits (Weng et al., 2013). Conversely, drugs used to manage some of these diseases reshape DNA methylation in neurons (Dong et al., 2008). Surprisingly, some of these changes might occur very early in the development of the individual, far before the clinical signs of the disease are manifest in the adult (Martinowich et al., 2003; Borrelli et al., 2008; Murgatroyd et al., 2009; Guo et al., 2011; Weng et al., 2013). In mice, maternal care, such as licking and grooming, influences the expression of glucocorticoid receptor (GR) in the neurons of the hypothalamus in the pups, and later in the adult (Weaver et al., 2007). GR is a major component of the stress response in the brain, and is implicated in short and long-term adaptations in response to stress (Dong et al., 2008; Murgatroyd et al., 2009). Maternal care causes the up-regulation of GR expression in the brain of pups, its maintenance in the adult and a lower propensity to develop depression-like phenotypes compared to pups deprived of maternal care. At the molecular level, maternal care induces the expression of transcription factor NGFI-A in the hippocampal neurons. In turn, NGFI-A binds to the GR promoter, induces its demethylation and its increased expression, that will be maintained later in life (Weaver et al., 2007).

Lessons gathered from the study of de novo DNA methylation events might likely apply to the DNA demethylation field. Transcription factors may play an important role in triggering local DNA demethylation events. For instance, in cancer, overexpression of the receptor tyrosine kinase RON (also known as macrophage stimulating 1 receptor, MST1R) in a number of human cancers correlates with metastasis and poor prognosis (Cunha et al., 2014). In a cellular model it was shown that overexpression of RON lead to hypermethylation and hypomethylation of a number of intergenic regions, and causes a better propensity to form metastasis when injected in the mice (Cunha et al., 2014). In a complementary analysis it was shown that RON triggers the accumulation of the DNA glycosylase MBD4 and that this regulation drives metastasis and part of the changes in DNA methylation. Yet, MBD4 lacks a DNA binding domain, and its selectivity might be mediated by dedicated transcription factors or histone marks (Hendrich et al., 1999; Laget et al., 2014).

Concluding Remarks and Emerging Concepts

DNA methylation plays an important role in the control of gene expression and cell fate in mammals. Its regulation and function has been upon intense scrutiny since its discovery in mid-1900s. Yet, how DNA methylation patterns are established during embryogenesis, and edited in adult tissue, remains a matter of intense debate. Profiling of DNA methylation in many cell type, species and environmental set up indicates that the DNA methylation profile is highly correlated with the cell type and its environment. As a consequence, de novo methylation and DNA demethylation events are not randomly distributed but are actually targeted to particular regulatory DNA elements in the genome, including promoters, enhancers or repeated DNAs. For this latter reason researchers have focused on the role of transcription factor in these DNA methylation events.

Yet, it is also recognized that non-coding RNAs, short and long, contribute to the establishment and editing of DNA methylation profiles in mammals. Non-coding RNAs may directly interact and control methylation and demethylation activities and, as a consequence, the pattern of DNA

methylation in the genome (Di Ruscio et al., 2013; Arab et al., 2014; Castro-Diaz et al., 2014; Molaro et al., 2014; Turelli et al., 2014). For instance, antisense long non-coding RNA TARID (TCF21 antisense RNA inducing demethylation), activates TCF21 expression by inducing promoter demethylation. TARID sequence is complementary to the sequence of the TCF21 promoter. Its transcription causes the anchoring of GADD45A (growth arrest and DNA-damage-inducible, alpha), a regulator of DNA demethylation, at the TCF21 promoter and its subsequent chromatin remodelling (Arab et al., 2014). Understanding the interplay between non-coding RNAs and transcription factors in the establishment and the maintenance of DNA methylation is therefore an important challenge for the future.

The characterization of the factors underlying the dynamic nature of DNA methylation and its plasticity with regards to environmental cues highlight potential pathways leading to changes in DNA methylation and how this information might be used for translational applications. For instance, in cell-based assays, it is possible to reprogram the methylation level of a CpG island by targeting a TET-fusion to the given CpG island (Zhang et al., 2012; Maeder et al., 2013). With the development of sophisticated systems of genome engineering, one can imagine in the future to use such strategies to revert aberrant methylation at a specific locus and treat a disease (with all the ethical issues such approaches will raised). Alternatively, inactivation of the transcription factor (or signaling pathways) responsible to the maintenance of aberrant DNA methylation pattern could prove useful to selectively target cancer cells. In biotechnology and industry also the gains could be immense. For instance, cell reprogramming is facilitated by addition of vitamin C, a compound that alters the activity of TET enzymes and DNA methylation maintenance (Blaschke et al., 2013; Chen et al., 2013). In the future one can imagine better control cell reprogramming by adding to the cocktail of reprogramming transcription factors (the 4 "Yamanaka" factors: KLF4, OCT3/4, SOX2, c-MYC), compounds that will modulate the activity of transcription factors involved in DNA methylation maintenance.

The identification of transcription factors as important drivers of changes in DNA methylation pattern in disease and during development offer tremendous opportunities in the future in basic research, in human medicine and in therapeutic applications.

Acknowledgements

BM and CM wish to thank Pierre-Antoine Defossez, Guillaume Velasco, Claire Francastel and the members of the Epigenetic and Cell Fate laboratory for support, discussions and suggestions during the writing of the manuscript. BM and CM also like to apologize that due to space limitations only a limited number of research papers could be cited. BM work is supported by the CNRS, a grant from Ligue contre le Cancer (Comité de Paris) and a Marie Curie International Re-integration Grant (PIRG07-GA-2010-268448). CM is a recipient of PhD fellowship from the Ministère de l'enseignement supérieur et de la recherche (MESR).
