Abstract

Ca\textsuperscript{2+} mediates the functional coupling between L-type Ca\textsuperscript{2+} channel (LTCC) and sarcoplasmic reticulum (SR) Ca\textsuperscript{2+} release channel (ryanodine receptor, RyR), participating in key pathophysiological processes. This crosstalk manifests as the orthograde Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+}-release (CICR) mechanism triggered by Ca\textsuperscript{2+} influx, but also as the retrograde Ca\textsuperscript{2+}-dependent inactivation (CDI) of LTCC, which depends on both Ca\textsuperscript{2+} permeating through the LTCC itself and on SR Ca\textsuperscript{2+} release through the RyR. This latter effect has been suggested to rely on local rather than global Ca\textsuperscript{2+} signaling, which might parallel the nanodomain control of CDI carried out through calmodulin (CaM). Analyzing the CICR in catecholaminergic polymorphic ventricular tachycardia (CPVT) mice as a model of RyR-generated Ca\textsuperscript{2+} leak, we evidence here that increased occurrence of the discrete local SR Ca\textsuperscript{2+} releases through the RyRs (Ca\textsuperscript{2+} sparks) causes depolarizing shift in activation and a hyperpolarizing shift inosochronic inactivation of cardiac LTCC current resulting in the reduction of window current. Both increasing fast [Ca\textsuperscript{2+}]i buffer capacity or depleting SR Ca\textsuperscript{2+} store blunted these changes, which could be reproduced in WT cells by RyRCa\textsuperscript{2+} leak induced with Ryanodol and CaM inhibition. Our results unveiled a new paradigm for CaM-dependent effect on LTCC gating and further the nanodomain Ca\textsuperscript{2+} control of LTCC, emphasizing the importance of spatio-temporal relationships between Ca\textsuperscript{2+} signals and CaM function.

Introduction

Dynamic modulation of cellular Ca\textsuperscript{2+} flows from either the extracellular space or the intracellular Ca\textsuperscript{2+} store into the cytoplasm participates in key pathophysiological processes, which depends on the ability of cells to properly sort ‘global’ and ‘local’ Ca\textsuperscript{2+} signals [1]. In this respect, the functional coupling of the sarcoplasmic reticulum (SR) Ca\textsuperscript{2+} release channels (ryanodine receptor, RyR), plays an important role in ventricular cardiomyocytes [2,3]. Depolarizing stimuli open voltage-gated LTCC, leading to Ca\textsuperscript{2+} entry (\textit{I}_{\text{Ca}}) and a subsequent rise in the cytoplasmic free Ca\textsuperscript{2+} concentration ([Ca\textsuperscript{2+}]i). While such [Ca\textsuperscript{2+}]i elevations are initiated by LTCC, they are also influenced by Ca\textsuperscript{2+} transporting organelles such as the mitochondria and the SR. Notably, in response to these increases in [Ca\textsuperscript{2+}]i, Ca\textsuperscript{2+} binds to and activates RyRs thereby amplifying the initial Ca\textsuperscript{2+} signal through the locally controlled Ca\textsuperscript{2+} -induced Ca\textsuperscript{2+} release (CICR) process to support the excitation-contraction coupling (ECC) and thus heart function [4]. On the other hand, the opening of LTCCs is tightly controlled to prevent intracellular Ca\textsuperscript{2+} overload. A major intrinsic negative feedback mechanism is the Ca\textsuperscript{2+}-dependent inactivation (CDI) of the widely distributed voltage-gated Ca\textsuperscript{2+} channels [5,6,7,8,9,10]. From the pioneering descriptions [11], CDI manifests as the hallmark time-dependent current decay during prolonged depolarization but also determines the voltage-dependent availability of Ca\textsuperscript{2+} channel during double-pulse protocols. Early studies of CDI were mainly focused on Ca\textsuperscript{2+} entry, but SR Ca\textsuperscript{2+} release also contributes significantly to the CDI [5]. In cardiac myocytes, depletion of SR Ca\textsuperscript{2+} stores or abolition of SR Ca\textsuperscript{2+} release causes a reduction of CDI [3,12], whereas increasing SR Ca\textsuperscript{2+} loading results in CDI enhancement [13]. CDI depends linearly on the rate and magnitude of SR Ca\textsuperscript{2+} release from the RyRs [12]. Thus, ~70% of CDI that occurs during ECC in rat ventricular myocytes arises from SR Ca\textsuperscript{2+} release, which might reduce Ca\textsuperscript{2+} influx during action potential up to 50% [14,15]. Furthermore, it has been shown that SR Ca\textsuperscript{2+} release dominates CDI initially, then, as [Ca\textsuperscript{2+}]i,
decreases due to SR Ca\(^{2+}\) reuptake, the SR dependent contribution declines with participation from Ca\(^{2+}\) entry via \(I_{Ca}\) dominating [16]. Now, SR Ca\(^{2+}\) release from the RyRs results in discrete and localized rises of [Ca\(^{2+}\)](Ca\(^{2+}\) sparks) triggered by \(I_{Ca}\) [4]. The large local releases of Ca\(^{2+}\) during CICR modulate in turn LTCC [3,12], suggesting that discrete Ca\(^{2+}\) cross-signaling occurs in the micro-domains of LTCC-RyRs [17].

Over the past decades there has been rapid progress toward understanding the molecular basis for CDI, cumulating with the identification of constitutively complexed calmodulin (CaM) with the Ca\(^{2+}\)channel as the specific resident CaM sensor [5,6,7,8,9,10]. CaM relies on its N and C lobes to detect spatiotemporal aspects of the Ca\(^{2+}\)signal for regulation of Ca\(^{2+}\) channels [3,12], and the channel as the specific resident Ca\(^{2+}\) sensor [5,6,7,8,9,10]. Therefore, whether and how discrete and local SR Ca\(^{2+}\) release participates to the Ca\(^{2+}\) control of LTCC?

We have chosen to further explore this question by comparing RyR\(^{R4496C}\) calsequestrin polymorphic ventricular tachycardia (CPVT) mutant mice to their wild type littermates (WT) by simultaneous recordings of \(I_{Ca}\) and the evoked [Ca\(^{2+}\)] transient and Ca\(^{2+}\) sparks. CPVT is a severe inherited cardiac disorder that manifests as malignant exercise-emotion-triggered arrhythmias (CPVT) mutant mice, the R4496C mutation of the RyR increased the Ca\(^{2+}\) sensitivity of RyRs [20]. This could be explained by a modified activity of Na\(^{+}\)/Ca\(^{2+}\) exchanger (NCX), which might rapidly and reversibly alter the Ca\(^{2+}\) concentration in the vicinity of the LTCCs [24]. However, the NCX currents (normalized to cell size) showed similar values in WT and CPVT myocytes (peak current density normalized by peak caffeine-evoked [Ca\(^{2+}\)]) transient, as evaluated by synchronous confocal images, in pA/pF: \(-0.83\pm0.09\) vs \(-0.82\pm0.13\), in 10 WT vs 12 CPVT cells, respectively, \(P<0.05\).

### Changes of voltage-dependent availability of Ca\(^{2+}\) channel reduce window current

A change in the time- and/or voltage-dependence of \(I_{Ca}\) kinetics could account for the observed alterations of \(I_{Ca}\). Over the whole voltage range, neither activation (Figure 2A) nor inactivation (Figure 2B) kinetics of \(I_{Ca}\) were significantly different between WT and CPVT cells. In addition, the increase in current area upon repetitive stimuli (during trains of voltage pulses), or frequency-dependent facilitation, was not modified in CPVT cells (data not shown).

Difference in the availability of \(I_{Ca}\) as function of the voltage might underlie the reduced peak current density at low voltages. The activation-voltage relationships were constructed by converting the peak current values from each current-voltage relationship data set to the chord conductance using the equation: \(G = I/(V - E_{rev})\) and then the ratio \(G/G_{\text{max}}\) were plotted against the membrane potential (\(E_{rev}\) and \(G_{\text{max}}\) as determined by the current-voltage fits the Boltzmann function \(d = 1/(1+\exp(V_0.7/V/V_0.6))\), where \(V_0.5\) is the potential at which the conductance is half maximally activated and \(k\) is the slope factor describing the steepness of the curve. Whereas \(V_0.5\) was unchanged, a significant rightward shift in \(V_0.7\) was observed in CPVT cells compared to WT (Table 1).
test current, \( I_{\text{max}} \), is proportional to the fraction of available channels at that given time. As shown in Figure 2C, the relations are sigmoid over -50 to 0 mV voltage range, but at prepulse potentials more positive than 0 mV the extent of inactivation decreased resulting in an U-shaped inactivation curve, consistent with inactivation arising from voltage- and Ca\(^{2+}\)-dependent processes (VDI and CDI, respectively) [11]. In contrast to activation, we observed that the voltage range where channels are experiencing inactivation is significantly more negative in CPVT than in WT cells. In addition, the turn up of inactivation curve at positive potentials is significantly reduced in CPVT.

Data negative to 0 mV from individual cells were fit to the Boltzmann equation

\[ f(V) = \frac{1}{1 + \exp \left( \frac{V - V_{0.5}}{k} \right)} + A \]

where \( V_{0.5} \) is the potential of half-maximal inactivation, \( k \) is the slope factor, \( A \) is the amplitude of the non-inactivating \( I_{\text{Ca}} \). A significant leftward shift is observed for \( V_{0.5} \) in CPVT compared to WT cells (Table 1).

The overlap of activation and inactivation voltage curves delimits a window current region that allows the channels to be tonically active at these membrane potentials, as the channel population dynamically equilibrates among open, closed and inactivated states, resulting in a steady-state current [26]. Due to opposite shifts in activation and inactivation curves (Figure 2C), the inactivation-activation overlap “window area” for \( I_{\text{Ca}} \) was substantially reduced in CPVT cells compared with controls. The Ca\(^{2+}\) window current \( I_{\text{WCa}} \) was estimated by the product of available channels \( \langle dF/dt \rangle \cdot f(V) \) and the relative peak conductance using the classical Hodgkin and Huxley formulation:

\[ G_{\text{max}} \cdot \langle dF/dt \rangle \cdot f(V) \cdot (V - E_{\text{rev}}). \]

A marked reduction in \( I_{\text{WCa}} \) was observed in CPVT myocytes compared with WT myocytes (Figure 2D). Of note, under \( \beta \)-adrenergic stimulation, which induced

no more differences in activation or inactivation parameters (Table 1) were observed between WT and CPVT myocytes.

Ca\(^{2+}\) dependence of reduced window current

Our observations furthered investigation on the molecular mechanism by which the R4496C mutation in RyR alters the \( I_{\text{WCa}} \). In cardiomyocytes, due to the close functional association of LTCCs with RyRs in the dyadic space, the Ca\(^{2+}\) flux through either channel modifies the activity of the other channel. Thereby SR Ca\(^{2+}\) release influences at least partly \( I_{\text{Ca}} \) [5]. Whereas [Ca\(^{2+}\)], transient is unaltered in CPVT cells (Figure 1C), CPVT myocyte
show a marked increased in RyR Ca\textsuperscript{2+} leak, which might be visualized as Ca\textsuperscript{2+} sparks [4,20]. We analyzed voltage-activated Ca\textsuperscript{2+} sparks in patch-clamped cells, applying small depolarizing steps from \(-48\) to \(-22\) mV for 300 ms, in 2 mV increments. At these voltages, the number of activated LTCCs is limited and it is possible to resolve the evoked Ca\textsuperscript{2+} sparks [22]. Figure 3A shows that the Ca\textsuperscript{2+} spark frequencies were significantly higher over the studied voltage range in CPVT compared to WT cells. As previously reported on spontaneous Ca\textsuperscript{2+} sparks [20], no other change in spatiotemporal spark properties were denoted in ICa\textsubscript{evoked} Ca\textsuperscript{2+} sparks (data not shown). These results lead us to probe the plausible Ca\textsuperscript{2+} dependence of the cross-signaling between ICa and RyR in the reduced IW\textsubscript{Ca}. To explore this possibility, further experiments were carried out by increasing the Ca\textsuperscript{2+}-buffering capacity of the cytoplasm through the introduction of exogenous buffer inside the patch pipette. We used the fast Ca\textsuperscript{2+} chelator 1,2-bis (2-ethane-N,N,N',N'-tetraacetic acid (BAPTA, 10 mmol/L). When compared to control conditions, increasing the cytoplasmic Ca\textsuperscript{2+}-buffering capacity with BAPTA in CPVT cells completely blunted the shifts in d\textsubscript{f'} activation and f\textsubscript{f'} inactivation variables eliminating the difference with WT cells (Table 1). As a result, IW\textsubscript{Ca} was merely identical to that observed in WT cells when [Ca\textsuperscript{2+}]\textsubscript{i} is clamped with BAPTA (Figure 3B). This suggests that local [Ca\textsuperscript{2+}] increases lead to the reduced IW\textsubscript{Ca} in CPVT mice. To test the contribution of the SR in the Ca\textsuperscript{2+}-dependent effects in IW\textsubscript{Ca}, we functionally disabled intracellular Ca\textsuperscript{2+} stores by application of the SR Ca\textsuperscript{2+} ATPase inhibitor (thapsigargin, 5 \(\mu\)mol/L) to block the ability of the cell to pump Ca\textsuperscript{2+} into the SR and to deplete the store by consecutive depolarizations to 0 mV. Consequently, SR Ca\textsuperscript{2+} release was blunted. In the same way as for buffering [Ca\textsuperscript{2+}]\textsubscript{i}, abolishing SR Ca\textsuperscript{2+} release restored IW\textsubscript{Ca} in CPVT cells to WT levels (Figure 3C) by preventing the shifts in d\textsubscript{f'} and f\textsubscript{f'} variables (Table 1).

It is noteworthy that both BAPTA dialyses and thapsigargin-treatment induced in WT cells a significant shift in the hyperpolarizing direction and a steepening of the activation curves (Table 1), resulting in a slight increased peak IW\textsubscript{Ca} (compare Figures 1 to 3B and C). This emphasizes the physiological relevance of RyR Ca\textsuperscript{2+} leak-mediated IW\textsubscript{Ca} reduction. To confirm this interpretation, we exposed WT cells to 50- \(\mu\)mol/L Ryanodol, which has been shown to increase the overall Ca\textsuperscript{2+} spark rate without global change.
on SR Ca\textsuperscript{2+} load [27]. Similarly to CPVT cells, upon Ryanodol exposition, the activation of ICa\textsubscript{L} in WT cells was shifted toward positive voltages while the inactivation was shifted toward negative voltages (Table 1, Ryanod) resulting in a decrease of IP\textsubscript{Ca} (Figure 3D).

CaM antagonists promoted window current reduction

Collectively, our findings suggest that increased RyR Ca\textsuperscript{2+} leak limits IP\textsubscript{Ca}. But what could the essential mechanistic ingredient of this effect be? The ubiquitous Ca\textsuperscript{2+} binding protein calmodulin (CaM) has a central role in determining LTCC Ca\textsuperscript{2+} sensitivity [5,6,7,8,9,10]. We therefore proceeded to probe the plausible involvement of CaM in reduction of IP\textsubscript{Ca}. As a first approximation of events that may be CaM dependent, we used [X-(6-aminohexyl)-5-chloro-1-naphthalenesulfonamide] (W7, 1 \textmu mol/L), a water-soluble, cell membrane–permeant competitive antagonist of Ca\textsuperscript{2+}/CaM [28]. Surprisingly, 30-min W7 cell-treatment did not affect either availability variables (Table 1) or IP\textsubscript{Ca} in CPVT cells (Figure 4A), whereas it shifted both activation curve to more positive voltages and inactivation curve to more negative voltages (Table 1) in WT cells compared to control conditions. Consequently, W7-treated WT cells behave such as CPVT cells, showing a reduced IP\textsubscript{Ca} (Figure 4A). Because the results obtained with W7 should not be taken as absolute proof of a CaM-dependent process, we repeated the experiments with a cell-permeable CaM-inhibitory peptide, CALP2, designed to bind to EF-hand four-amino acid sequence of CaM [29]. Similarly to W7-treatment, a 60-min incubation with 100-\textmu mol/L CALP2 did not affect either IP\textsubscript{Ca} (Figure 4B) or availability variables (Table 1) in CPVT cells. However, in WT cells CALP2 significantly shifted the activation curve rightward and the inactivation curve leftward (Table 1) leading to a reduction of IP\textsubscript{Ca} towards the level corresponding to that of CPVT cardiomyocytes (Figures 4B). As an important control, neither in CPVT nor in WT CaM antagonists altered the diastolic RyR activity in intact cells, visualized in situ by confocal microscopy as spontaneous Ca\textsuperscript{2+} sparks frequencies (Figure 4C).

As well, the amount of soluble (Figure 4D) and membrane bound CaM (Figure 4E) are not altered in CPVT mice hearts compared to control WT, consistent with unaltered ICa\textsubscript{L} decay kinetics (Figure 2B).

Discussion

The purpose of our study was to examine whether discrete and local increase of SR Ca\textsuperscript{2+} release has any effect on ICa\textsubscript{L} with respect to nanodomain control of LTCCs. Using CPVT mice as a model with high spontaneous RyR-generated Ca\textsuperscript{2+} leak, our results pinpoint that the increase in RyRCA\textsuperscript{2+} leak caused opposite shifts in activation and in activation voltage curves of the cardiac LTCC. The resulting reduction of window current is prevented by manoeuvres that minimize variations in [Ca\textsuperscript{2+}], due to SR Ca\textsuperscript{2+} release. Surprisingly, application of CaM antagonists did not have any effect on the cells from the CPVT mouse but altered the inactivation and activation curves in the WT mouse to make these more like the CPVT mouse, revealing a new paradigm for CaM-dependent effect on LTCC gating. These effects might represent an adaptive mechanism to cytotoxic SR Ca\textsuperscript{2+} leak and Ca\textsuperscript{2+} overload.

RyRCA\textsuperscript{2+} leak limits IP\textsubscript{Ca}

Analysis of skeletal myotubes derived from RyR-knockout (dyspedic) mice has revealed that in addition to the orthograde signal of ECC, there is also a retrograde signal whereby RyR promotes the Ca\textsuperscript{2+} conducting activity of the skeletal LTCC [30]. But this bi-directional coupling is thought to result from direct physical protein-protein interaction [30]. Nevertheless, it has been recently suggested that this feedback mechanism, which results in reduction of IP\textsubscript{Ca}, might also depend on local SR Ca\textsuperscript{2+} signaling [2]. Despite some controversial results, no such structural interaction has been found in cardiac cells. However, the close physical association between LTCCs and RyRs that in cardiac...
muscle takes place at the narrow site of the tubulo-reticular junction where each LTCC is closely associated with a group of RyRs [4], creates a bi-directional Ca$^{2+}$ signaling microdomain such that Ca$^{2+}$ flux through one channel modifies the functional behavior of the other channel. In this study, we show that either buffering intracellular Ca$^{2+}$ or eliminating SR Ca$^{2+}$ release erased the difference in $I_{Ca}^{W}$ between CPVT and WT mice. Thus, we conclude that the mechanism underlying the reduced $I_{Ca}^{W}$ in CPVT mice is SR Ca$^{2+}$ dependent. In cardiac cells, SR Ca$^{2+}$ release is indeed the major component determining CDI [3,12,13,14,15,16]. However, these studies as well as the majority of CDI analyses, relied almost exclusively on the accelerated current inactivation during depolarizing voltage steps whereas the CDI manifestation on current availability [11] has not been yet the subject of in depth investigation. Nonetheless, when compared to neonatal cardiomyocytes, where there is poor T-tubule development, adult cardiomyocytes show a reduced $I_{Ca}^{W}$ [31] and a slight reduction in $I_{Ca}$ availability has been observed with static elevation of [Ca$^{2+}$]i [32].

Although a global increase in [Ca$^{2+}$], can participate to CDI, there is evidence suggesting that local Ca$^{2+}$ signaling between RyRs and LTCCs might mediate a Ca$^{2+}$ functional crosstalk between LTCCs and RyRs [3,16,17]. Changes in local subsarcolemmal Ca$^{2+}$ caused by the alteration of normal Ca$^{2+}$ extrusion via NCX could be involved. But we observed no difference in NCX activity between WT and CPVT cells. Such an alteration in Ca$^{2+}$ driving force, as well as in surface charges, will be difficult to reconcile with the absence of modification in peak $I_{Ca}$ density, apparent reversal potential and opposite shifts of activation and inactivation voltage ranges. Long term changes are known to complicate the mechanistic attribution of cause and effect in genetically modified animals. One might thus suggest that the observed enhancement of inactivation of LTCCs could reflect a survival adaptation to increased [Ca$^{2+}$], rather than a mechanistic insight into the functional coupling between LTCCs and RyRs. However, acute intervention buffering Ca$^{2+}$ (Figure 3B) or depleting the SR Ca$^{2+}$ store (Figure 3C) restores $I_{Ca}^{W}$ in CPVT cells to WT levels by preventing the shifts in $dV$ and $fV$ variables.

These considerations let us suggest a tonic effect rather than long term adaptation. The alteration in Ca$^{2+}$ signaling observed in CPVT cells is the increase in RyR Ca$^{2+}$ leak. Indeed, the $I_{Ca}$ evoked [Ca$^{2+}$], transients (Figure 1) were not altered. This is consistent with our previous observations and the normal cardiac function described under basal conditions in the CPVT mice, whereas a rate-dependent defect exists [20]. The increased RyR Ca$^{2+}$ leak seems then to be insufficient to precipitate by itself...
changes in [Ca^{2+}]_i transient under basal stimulation condition, effect which might reflect a sufficient time interval to maintain the physiological SR Ca^{2+} load, as we observed by caffeine application. Then, we conclude that the tonic reduction in I_{Ca}^W is mediated through local changes of [Ca^{2+}]_i in the restricted space where LTCCs and RyRs are located in the dyadic junctions, a

Figure 4. Calmodulin inhibition reduced I_{Ca}^W in WT cells. A & B, CaM antagonists, W7 (A) or CALP2 (B) reduced I_{Ca}^W in WT cells (dashed line) without affecting it in CPVT cells (continuous line). C, Comparison of the Ca^{2+} sparks occurrence at rest in myocytes from WT (open bars) and CPVT (closed bars) cells in control conditions and after incubation with W7 (left hatched bars) or CALP2 (right hatched bars). * P<0.05 vs WT. D & E, Representative immunoblots and quantification of CaM protein levels in cardiac heart lysates (D, normalized to the corresponding actin level and normalized to respective controls) and detected in the membrane fraction (E, normalized to the corresponding Ca_{v}1.2 level and normalized to respective controls) from WT (open bars, n = 4) and CPVT (closed bars, n = 4) mice.

doi:10.1371/journal.pone.0020863.g004
mechanism paralleling the local and global [Ca\(^{2+}\)], sensing for the CDI of LTCCs [6,7,8]. This interpretation is further supported by the use of Ryanodol, which mimics RyR Ca\(^{2+}\) leak [27], although we cannot exclude a direct effect of this ryanoid on LTCCs.

A new paradigm of CaM effect on LTCC gating

Our results indicate that RyR Ca\(^{2+}\) leak influence gating properties of the LTCCs. One intriguing but remarkable aspect of our findings is that the changes in the voltage-dependence of LTCC activation and inactivation were not paralleled by changes in the kinetic properties of I_{Ca} (Figure 2A & B), similar to that observed by others [33]. Whereas this might indicate that recovery from the inactivated state was impeded, this interpretation will be difficult to reconcile with the maintenance of I_{Ca} peak density at more depolarized voltages (Figure 1D). This emphasizes the complex nature of I_{Ca} inactivation mechanisms, and thus might not reflect the same process. The absence of influences on I_{Ca} decay suggested that discrete Ca\(^{2+}\) control is unlikely on LTTC open state, whereas shifted steady-state inactivation suggested a stronger effect on inactivated state than on rested state. However, the conformational distinct Ca\(^{2+}\) channel populations (resting, open and inactivated states) are closely interrelated. We reasoned on the possible crosstalk between the CDI and VDI gating of the LTCCs, such that a change in the stability of the open state is predicted to affect both VDI and CDI gating [34]. In this way, we suspected that the RyR Ca\(^{2+}\) leak induced enhancement of inactivation might induce the rightward shift in the activation. In fact, conformational changes caused by Ca\(^{2+}\) binding to the resident CaM, the primary initiator event for CDI [56,7,8], may allosterically reduce activation gating [10] and functionally link the VDI machinery [9,35]. We observed that CaM antagonists had no effect on CPVT but reduced I_{Ca}^W in WT. These results echo the shift in I_{Ca} availability curve to more negative potential with calmidazolium, another CaM antagonist [36] and are consistent with previous results in recombinant systems. Similarly to our results, splice variants or mutants of the LTCC IQ motif for CaM binding show a rightward shift in activation and a leftward shift in inactivation [37,38], whereas CaM overexpression shifts the activation to more negative potential [39]. This prompt us to suggest that the RyR Ca\(^{2+}\) leak dependent reduced I_{Ca}^W inversely related to CaM is due to an intrinsic effect on LTCC. Besides its role as a signal transduction molecule, CaM also functions as a ubiquitous endogenous fast Ca\(^{2+}\) buffer, an effect frequently overlooked [40]. We therefore propose that Ca\(^{2+}\) buffer capacity of CaM normally prevents Ca\(^{2+}\) to access to other regulator sites, since free CaM is locally enriched in the vicinity of the channels [41]. CaM antagonists in WT cells or increased RyR Ca\(^{2+}\) leak in CPVT cells outdo this CaM effect, allowing Ca\(^{2+}\) feedback to other Ca\(^{2+}\) sensor domains involved in CDI [7,24,35].

Pathophysiological perspectives

Taken together, our study identifies a new Ca\(^{2+}\) regulatory mechanism acting as a powerful switch that determines LTCC gating by interfering with CaM modulation. This effect might serve as a compensatory response to counteract excessive SR Ca\(^{2+}\) release and SR store overload [42], and thus participates to the SR Ca\(^{2+}\) load decrease observed at high stimulation frequencies [20]. One might speculate on a yin-yang effect of the diastolic Ca\(^{2+}\) leakage on trigger activities for fatal acquired or genetic cardiac arrhythmias and sudden death. Elevation of diastolic [Ca\(^{2+}\)]_i through increased Ca\(^{2+}\) spark frequency is regarded as an arrhythmogenic mechanism: Ca\(^{2+}\) sparks are believed to participate as crucial events in the initiation and propagation of Ca\(^{2+}\) waves in cardiomyocytes and the elimination of cytosolic Ca\(^{2+}\) via the NCX generates a depolarizing current, which can give rise to delayed after depolarizations (DADs) [4]. Conversely, the I_{Ca}^W has a central role in arrhythmogenesis in the setting of action potential (AP) prolongation because it can reverse repolarization to create fluctuation of membrane voltage during the repolarization phase of the AP, or early after depolarizations (EADs) [26]. EADs may give rise to salvos of premature APs leading to after contractions through a subsequent secondary SR Ca\(^{2+}\) release, triggered activity and promote reentrant arrhythmias such as Torsades de points [43]. Thus, diastolic Ca\(^{2+}\) leak would promote DADs [21], while would be protective from EADs by reducing I_{Ca}^W. Our results indeed echo a prevention of EAD induced Torsades de points by W7 through a decrease of I_{Ca}^W [33,44].

Methods

Experiments were performed on male and female heterozygous RyR\(^{R4496C}\) mice (CPVT) and their WT littermates (F3 to F5 generation), as previously described [20,22], in accordance to the ethical principles laid down by the French (Ministry of Agriculture) and ECC directive 96/609/EEC and was approved by the Comité Régional d’Ethique sur l’expérimentation animale of Languedoc-Roussillon on the Use and Care of Animals. All persons who participated in the experiments had the training and authorization to do so (authorization B34-172-16 for animal facility manager).

Mice

The generation of RyR\(^{R4496C}\) knock-in mice was previously described [45]. Mice were age-matched littersmates (between 4 to 6 months old and weighing 22-25 g) maintained on a C57BL/6 background after >3 backcrosses to C57BL/6.

Cell isolation

Isolated ventricular myocytes from knock-in mouse-model carrier of the RyR R4496C mutation (CPVT) and their gender-matched littermates wild-type (WT) were prepared using an enzymatic perfusion method. Animals were treated with heparin (1000 units kg\(^{-1}\)) and anaesthetized with Na\(^{+}\) pentobarbital (50 mg/kg) administered intraperitoneally. The heart was excised rapidly via a thoracotomy and the pericardium was removed. The heart was placed in ice-cold (0 \(^\circ\)C) oxygenated Tyrode solution containing (mmol/L): NaCl 130, Na\(^{2+}\)HPO\(_4\) 0.4, NaHCO\(_3\) 5.8, MgCl\(_2\) 0.5, KCl 5.4, glucose 22, Heps 25 and insulin 10\(^{-3}\) (titrated to pH 7.4 with NaOH). The aorta was cannulated above the aortic valve and was perfused by gravity (70 cm column height) with warm (37 \(^\circ\)C), preoxygenated Tyrode solution supplemented with 0.1 mmol/L EGTA for 2 min. Enzyme solution containing 1 g/L collagenase Type II (Worthington) in Tyrode solution supplemented with 0.1 mmol/L CaCl\(_2\) was then perfused until the aortic valve was digested (attested by the increased outflow of perfusate). The heart was transferred to a Petri dish containing enzyme solution supplemented with 2 g/L bovine serum albumin (BSA) and gently shaken for 2-3 min at 37 \(^\circ\)C to disperse individual myocytes. The resulting cell suspension was filtered through a 250 \(\mu\)m nylon mesh and centrifuged for 5 min at 20 g. The cell pellet was suspended in Tyrode solution supplemented with 0.5 mmol/L CaCl\(_2\) and 2 g/L BSA and was centrifuged again at the same speed. Finally, the cell pellet was suspended in storage solution comprising Tyrode solution supplemented with 1 mmol/L CaCl\(_2\) and 2 g/L BSA.

Patch-clamp and fluorescence measurements

Whole-cell currents were monitored with an Axopatch 200A patch-clamp amplifier. Capacitance compensation was optimized and series resistance was compensated by 40–80%. Ca\(^{2+}\) images
were simultaneously acquired with a confocal microscope (MetaZeiss LSM510, objective oil immersion x40, numerical aperture 1.2) in line-scan mode (1.5 μs/cell). $I_{Ca}$ and fluorescence signals were simultaneously digitized (Digitata 1200, Axon Instruments) and acquired at sampling rate of 100 μsec using pClamp 8.1. During experiments, cells were superfused with an external solution containing (in mmol/L) 140 NaCl, 0.5 MgCl2, 5 CaCl2, 1.8 CaCl2, 5.5 glucose, 5 Hepes (pH 7.4), while the patch pipette was filled with a solution containing (in mmol/L) 130 CsCl, 1 MgCl2, 1 NaH2PO4, 3.6 Na2HPO4, 5 MgATP, 10 HEPES and 0.05 Fluo-3 pentapotassium salt (Molecular Probes); pH 7.2. $I_{Ca}$ and SR Ca2+ releases were elicited by 100 msec voltage steps in 10 mV increments from −50 to +60 mV, every 10 seconds. Prior to it, to allow steady-state SR load a voltage protocol including 4 voltage steps (150 msec) from −80 to 0 mV was apply and voltage-gated Na+ channels were inactivated by a 500-msec ramp from −80 to −42 mV [22].

The activation kinetic of $I_{Ca}$ was measured for every depolarizing step as the time from the onset of the voltage step to the peak of current. The time course of inactivation of $I_{Ca}$ was determined by analysis of the decay phase of current traces in response to voltage steps. Best fits were obtained with an equation including a sum of two exponentials plus a constant expressed as $A_{fast}e^{-t/\tau_{fast}}+A_{slow}e^{-t/\tau_{slow}}+A_0$, where $t$ and $\tau$ are the time constant and the initial amplitude of the two components subscripted fast and slow, respectively, and $A_0$ is the amplitude of the time-independent component.

Isochronic inactivation were performed with a double pulse protocol, in which a conditioning prepulse of variable amplitude (in the −50 to +60 mV range, from −80 mV) and 250 msec in duration (long enough to produce complete inactivation at each potential) was followed by a test pulse to 0 mV (selected based on the voltage at which peak $I_{Ca}$ was maximum) and 100 msec in duration.

Fluo-3 fluorescence was excited with the 488-nm line of an argon ion laser. Emitted fluorescence was measured at wavelengths over 515 nm. Image acquisition was made in the line-scan mode. A single myocyte was scanned repetitively along a line parallel to the longitudinal cell axis. Image processing and analysis were performed using IDL software (Research Systems), as previously described [22,23]. Briefly, each image was background-subtracted. The fluorescence transient was obtained by averaging the fluorescence values in a 1.4-μm frame over time. Amplitude was measured as the maximum value of $F/F_0$, where $F$ is the fluorescence signal and $F_0$ is the basal fluorescence (measured as the average of the 50 lowest values on the fluorescence transient).

For SR Ca2+ load estimation, myocytes were previously stimulated (4 voltage 150 msec steps from −80 to 0 mV) for 1 min, then 10 mmol/L caffeine was added, the fluorescence image was recorded by confocal microscopy and the associated NCX current was recorded by patch clamp and integrated to estimate the amount of Ca2+ released by the SR [23].

Spontaneous Ca2+ sparks (Figure 3A) were imaged on intact Fluo-3AM loaded cells superfused with Tyrode solution (in mmol/L: NaCl 140, MgCl2 1.1, CaCl2 1.8, KCl 4, glucose 10 and Hepes 10; pH 7.4).

Drugs. - BAPTA and W7 were purchased from Calbiochem; CALP2 and Ryanodine were from Tocris Bioscience; and other chemical products were from Sigma. Ryanodol was generated as previously described [27].

Western blotting. - Mouse heart homogenates were prepared with homogenization buffer (in mmol/L: sucrose 300, sodium-fluoride 20, HEPES 20, Aprotinin 5.2 10−4, Benzamidine 10−2, Leupeptin, 12 10−5; PMSF 0.1, 0.5% sodium desoxicholate, 0.1% SDS, pH 7.2) using a Potter-Elvehjem and spun at 2,000 × g for 10 min. Membrane fractions were isolated by ultracentrifugation at 40,000 g for 30 minutes at 4°C [21]. Protein concentration was assayed by the Bradford method. 25 μg of protein were fractionated on gradient (8 to 20%) SDS-PAGE gels, transferred onto PVDF membranes (30 min in the semidry transfer chamber at 15 V using the 0.45 μm Amershams Hybond-P membrane, GE Healthcare Bio-Sciences, Waukesha, WI, USA) and probed with anti-caldesmon monoclonal antibody (1:500, Thermo Scientific, Waltham, MA, USA) or anti-CaV1.2 polyclonal antibody (1:1000, Millipore Co, Billerica, MA, USA), in TBS buffer (in mmol/L: Tris·HCl 50, NaCl 150, +0,1% v/v Tween 20, pH 7.4) with 1% w/v non-fat dried milk powder. Membranes were blocked overnight with 5% w/v non-fat dried milk powder in TBS buffer before primary antibody addition. Membranes were incubated 1 h with corresponding secondary peroxidase-conjugate goat anti-rabbit (diluted 1:3,000 in TBS, EMD Chemicals Inc, Gibbstown, NJ, USA). Signals were developed by chemiluminescence (Supersignal West Pico Chemiluminescent substrate, Thermo Scientific, Waltham, MA, USA). The relative amount of protein on the blots was determined by densitometry using KodakID Software (v. 3.635, Molecular Imaging Systems, New Haven CT, USA). Actin signals were detected in the same blots with anti-actin serum (1:20000, Sigma-Aldrich, Inc. México) and used as loading controls.

Statistical Analysis. - Data are presented as means ± SEM and compared using t test or an unequal variance t statistic (Welch test), when appropriate, with the PAST program (http://folk.uio.no/hammer/past/). Differences with values of $P<0.05$ were considered significant.
