24 The short article entitled «Effect of alterations in the arterial carbon dioxide tension  
25 on the blood flow through the cerebral cortex at normal and low arterial blood pressures»,  
26 published in 1965 in the JNNP by A. Murray Harper and H.I. Glass<sup>1</sup>, is among the most cited  
27 articles ever published in the journal (429 citations as of 21 January 2020). Interestingly, the  
28 same first author published the subsequent year in the JNNP another highly cited article<sup>2</sup> on  
29 a closely related subject (372 citations as of 2020).  
30  
31

32 The Harper and Glass 1965 article was the first to assess the effects of changes in the  
33 arterial partial pressure of CO<sub>2</sub> (PaCO<sub>2</sub>) on the cerebral circulation in conditions of normal  
34 arterial blood pressure, moderate hypotension and severe hypotension. To this end, the  
35 authors applied in anaesthetized mongrel dogs the technique that Lassen and Ingvar had just  
36 developed to measure quantitative regional blood flow of the exposed cerebral cortex using  
37 radioactive krypton injected in the internal carotid artery<sup>3</sup>.  
38  
39

40 The strong effects of changes in PaCO<sub>2</sub> on the cerebral vasculature, first discovered in  
41 1928 by Forbes and Wolff via direct observation of the pial arteries through a glass window  
42 in animals, was subsequently confirmed in humans, first indirectly by Lennox and Gibbs in  
43 1932<sup>4</sup> by means of jugular vein PO<sub>2</sub> measurements, and then directly by Kety and Schmidt<sup>5</sup> in  
44 1946 using their whole-brain cerebral blood flow (CBF) technique that used inhaled N<sub>2</sub>O.  
45 These studies established that hypercapnia is the most potent brain vasodilator, and  
46 conversely hypocapnia a very potent vasoconstrictor. In 1964, Reivich<sup>6</sup> documented in  
47 monkeys that hypercapnic vasodilation, and hence the CBF increase, reached a plateau  
48 around 150 mmHg PaCO<sub>2</sub>, and conversely that vasoconstriction was maximal for PaCO<sub>2</sub>  
49 levels around 18 mmHg. In parallel, Fog, Forbes and others, using the glass window  
50 approach, showed in the 1930's that reductions in mean arterial blood pressure (MABP)  
51 induced pial artery vasodilatation, and conversely, i.e., the cerebral auto-regulation<sup>2</sup>.  
52  
53  
54  
55  
56

57 In their seminal 1965 JNNP article, Harper and Glass<sup>1</sup> aimed to assess whether the  
58 vasodilation induced by hypotension affected the cerebrovascular response to changes in  
59 PaCO<sub>2</sub>. They indeed found that, as compared to the normotensive condition, the slope of the  
60

1  
2  
3 CBF response to PaCO<sub>2</sub> changes was shallower at moderate arterial hypotension, and  
4 completely flat at severe hypotension levels (**Figure**), documenting that the same resistive  
5 pial vessels were involved in the two regulations, and that maximal  
6 vasodilation/vasoconstriction in response to changes in one physiological variable abolished  
7 the response to the other physiological variable.  
8  
9

10 Why has this paper been, and still is - 28 citations since 2016 - so widely cited? First  
11 of all, it describes a key physiological phenomenon that has wide implications in animal and  
12 human cardiovascular and respiratory physiology and pharmacology. Second, Harper and  
13 Glass' observations have major clinical implications in numerous medical disciplines,  
14 particularly neuro-anaesthesia, neuro-intensive care and, of course, cerebrovascular  
15 diseases - specifically, that, on top of PaO<sub>2</sub>, both BP and PaCO<sub>2</sub> have to be closely monitored  
16 and controlled to avoid worsening of the already present brain damage. For instance, in  
17 acute traumatic brain injury with threateningly elevated intra-cranial pressure (ICP) - which  
18 causes maximal vasodilation, further increasing the ICP in a vicious cycle -, brief hypocapnia  
19 can be life-saving by rapidly reducing the cerebral blood volume<sup>7</sup>.  
20  
21  
22  
23

24 In clinical neurology and stroke medicine, the implications of the concept of maximal  
25 vasodilation has had to this day major impact in the understanding and management of  
26 cerebrovascular diseases including transient ischemic attacks (TIAs) and acute ischemic  
27 stroke. Indeed, thanks to the development of non-invasive techniques to measure regional  
28 CBF and oxygen metabolism in man using positron emission tomography (PET), it was shown  
29 that in a subset of patients with repeated TIAs affecting the territory of an occluded or  
30 severely stenotic internal carotid artery, there was permanent hypoperfusion in the distal  
31 cortical areas associated with increased oxygen extraction fraction, documenting exhausted  
32 vasodilatory reserve in turn causing clinical symptoms on a hemodynamic – as opposed to  
33 embolic - basis<sup>8</sup>. Subsequently, Lassen and co-workers developed a pharmacological  
34 vasodilatation challenge using acetazolamide (Diamox<sup>®</sup>) to test the cerebral vasodilatory  
35 reserve, also called cerebrovascular reactivity (CVR)<sup>9</sup>, an approach still in use today using  
36 single-photon emission computed tomography (SPECT) and perfusion radiotracers such as  
37 99mTc-HMPAO. Transcranial Doppler ultrasound using the breath holding test is also  
38 routinely used worldwide to assess the CVR distal to, and hence the hemodynamic effects of,  
39 carotid stenosis or occlusion<sup>10</sup>. More recently, MRI- or CT-based perfusion imaging has been  
40 used to map impaired CVR across the whole brain in the form of prolonged arterial mean  
41 transit time under physiological conditions<sup>11</sup>, currently the most widely used approach to  
42 determine optimal medical and/or surgical management of such patients. Novel, completely  
43 non-invasive MR-based approaches, not as yet fully implemented in routine, involve inhaled  
44 CO<sub>2</sub> challenge using BOLD MRI or arterial spin labelling (ASL)<sup>12</sup>.  
45  
46  
47  
48  
49  
50  
51  
52

53 Regarding acute ischemic stroke (AIS), the concept of maximal vasodilatation also had  
54 important implications. First of all, it made the old idea of treating AIS patients with  
55 pharmacological vasodilators not only obsolete, but also potentially hazardous, because  
56 inducing vasodilation in the non-maximally vasodilated territories involves a risk of diverting  
57 blood flow away from the ischemic areas (so-called 'Robin Hood syndrome', or  
58 'hemodynamic steal')<sup>13</sup>, an effect also well documented in chronic carotid occlusion<sup>14</sup>.  
59  
60

Lassen's group subsequently tested 'inverse steal' - i.e., they assumed that reducing perfusion in unaffected areas by means of hyperventilation would elevate perfusion in ischemic areas -, but unfortunately this approach failed to show clinical benefit<sup>15</sup>. Second, the concept of maximal vasodilation pointed to the potential risk of worsened ischemia associated with drops in systemic blood pressure, a variable now closely monitored and controlled in AIS<sup>16</sup>.

To sum up, Harper and Glass' widely cited physiology paper reporting results from animal experiments 55 years ago in the JNNP has contributed to major advances in understanding the disorders of the cerebral circulation involved in numerous neurological and neurosurgical conditions, and in turn has impacted to the present day the management of the afflicted patients.
